This article is a supplement to a previously (vol. 111) published paper on the same subject. The results of the Hummelsheim operation in 12 cases of congenital or acquired paralysis of the lateral and medial rectus are described. The author recommends the procedure for all cases of paralysis of the lateral muscle. The usefulness in cases of paralysis of the medial muscle needs further investigation. In cases of postoperative divergent squint, however, a muscle implant from the upper and lower rectus muscle supports and supplements the advancement of the internal rectus. (References.)

Scobee, R. G. **Anatomic factors in the etiology of heterotropia.** Am. J. Ophth. 31:781-795, July, 1948. (11 figures, 6 references.)

Schulte, D. **Bilateral isolated paresis of the superior rectus, a rare disturbance of the eye muscles.** Klin. Monatsbl. f. Augenh. 112:299-304, 1947.

The author observed a bilateral isolated paresis of the superior rectus muscle. Upward rotation and torsion were disturbed in the position of abduction of the individual muscle. The resulting double images are like those due to bilateral overaction of the inferior oblique muscle. The cause of the paresis was probably vascular damage in both lateral nuclei of the oculomotor nerve. The most sensible treatment of the condition is bilateral tenotomy of the inferior oblique rather than a bilateral recession of the inferior rectus muscle. Max Hirschfelder.

Venco, Luigi. **On the factors which regulate the taking of corneal transplants.** *Ann. di ottal. e clin. ocul. 72:749-766*, Dec., 1946; 73:28-52, Jan., 1947.

Venco reviews the pertinent literature and discusses at length the various factors which may possibly bear on the taking of corneal transplants. He holds that success in keratoplasty is due above all to the great vitality and resistance of corneal

tissue, to its relatively low rate of metabolism, to its marked regenerative capacity, and to the fact that the transplant is in immediate contact with its sources of nutrition.

There is evidence that the cornea has greater resistance than any other tissue known to biologists and that, because of its low rate of metabolism, it can survive for some time even after refrigeration and when deprived of its external sources of nourishment. Likewise the grafted tissue is well tolerated because the corneal proteins (presumably because of a deficiency of closed-chain amino acids in their chemical composition) have little or no antigenic property.

The orientation or "polarity" of the transplant may be entirely disregarded. Corresponding layers in host and transplant must be apposed as accurately as possible, but the graft may be placed without regard to its original meridians in the donor's eye. The presence of normal tissue in some part of the surrounding cornea of the recipient's eye is essential if the graft is to remain transparent. Whether the donor and recipient are related by blood or whether they belong to the same blood group is immaterial. Since in general the factors that might prevent a successful transplant diminish with age, the older the donor the greater the chances of success.

CONJUNCTIVA, CORNEA, SCLERA

Brausewetter, G. **A case of band-shaped corneal opacity successfully treated with hydrochloric acid.** Proc. Ophth. Soc. Vienna p. 44, March 29, 1943.

A posttraumatic band-shaped extensive corneal opacity in a patient's eye was treated twice with 2-percent hydrochloric acid solution after removal of the epithelium. The vision improved from counting of fingers at 25 cm. to 6/36.

F. Nelson.

Bruens, E. **Treatment of gonorrheal ophthalmia with chemotherapeutic and antibiotic remedies.** Klin. Montsbl. f. Augenh. 112:327-332, 1947.

The sulfonamide therapy of the past eight years is reviewed. It is pointed out that the successful treatment of ophthalmia neonatorum by the exclusive use of sulfonamides during the earlier years has become less and less successful lately, because the gonococci became sulfa-resistant or because only sulfa-resistant strains survived the influx of the new drug. There are indications that the treatment with penicillin will suffer a similar experience. The author recommends quarter-hourly irrigation of the conjunctival sac with normal saline solution in addition to the half-hourly instillation of 20 percent Cibazol or Globucid (sulfathiazole compounds) solution or repeated instillation of penicillin solution. For severe cases he suggests general sulfa treatment and intramuscular milk injections, again in addition to the regular quarter-hourly irrigation of the conjunctival sac. (References.) Max Hirschfelder.

Giacomelli, Piero. **The rosaceal keratidites.** Arch. di ottal. 51:106-135, July-Aug.-Sept., 1947.

The author describes two cases of keratitis rosacea, briefly summarizes the clinical picture, and reviews the principal hypotheses advanced to explain this obscure problem. The disease is an expression of a decreased respiratory activity in the tissue which is brought on by an increase in venous pressure and by deficiency of lactoflavin. This is probably due to a disfuction of the suprarenal cortex which controls both these factors.

Francis P. Guida.

Hatschek, G. **Contribution to the treatment of diseases of the anterior segment.** Klin. Monatsbl. f. Augenh. 112:318-327, 1947.

The therapeutic measures for various

forms of conjunctivitis, blepharitis, corneal ulcers and herpes corneae are discussed. The lack of certain drugs in postwar Europe has been taken into account. The measures which are recommended follow in general those used in the United States. The use of silver nitrate for conjunctivitis is strongly stressed. Subconjunctival injection of the patient's blood (3 to 5 cc.), puncture of the anterior chamber and parenteral injection of the hormone of the adrenal glands has been of value in the treatment of cases of deep keratitis which resisted ordinary measures. The importance of improving the general health of the patient by adequate general measures is stressed. (References.) Max Hirschfelder.

Lepri, Giuseppi. **Epithelial sclerocorneal cysts of congenital origin associated with congenital malformation of the fundus.** Arch. di ottal. 51:53-80, April-May-June, 1947.

Lepri reviews the literature and then describes the general characteristics and accepted pathogeneses of non-traumatic sclerocorneal cysts. He describes one case of congenital cyst which showed an associated prepapillary cyst in the left eye and a very small cyst on the nerve margin of the right eye. Francis P. Guida.

Lindner, K. **Excision of corneal scars.** Proc. Ophth. Soc. Vienna, p. 72, May 22, 1944.

A woman, 40 years of age, had frequent severe eye inflammations during childhood resulting in dense central keloid scars in each cornea. Vision was reduced to counting of fingers at 25 cm. After superficial trephining with a 3-mm. trephine the keloids, together with an opaque layer of corneal tissue, were "pealed off." In the right eye a vision of 6/36 was obtained with contact lens. F. Nelson.

Lindner, K. **The treatment of a case of argyrosis of the conjunctiva.** Proc. Ophth. Soc. Vienna p. 69, April 17, 1944.

Following the procedure of Weymann (J.A.M.A. 1367, 1929) Lindner treated an opera singer who had developed a disfigured argyrosis of the conjunctiva with subconjunctival injections of a mixture of 12-percent sodium thiosulfate and 2-percent potassium ferric cyanide. It is necessary to use platinum-iridium needles for these injections. Four treatments were necessary and the patient was fully satisfied with the cosmetic result.

F. Nelson.

Lippi, E. V. **White rings of Coats.** Arch. di ottal. 51:97-105, July-Aug.-Sept., 1947.

The author describes one case and then presents his theory of the pathogenesis of the lesion. He believes that there is an alteration of the perforating nerves of the cornea and of the openings in Bowman's membrane which leads to a degenerative process of the surrounding tissue. This theory of pathogenesis does not preclude a neurovascular etiology. To a primary alteration of this nature a toxic action or a trophic disturbance may be added.

Francis P. Guida.

Michtner, H. **Uncommon lead impregnation of the cornea.** Proc. Ophth. Soc. Vienna p. 87, Dec. 11, 1944.

An 18-year-old woman who had been in an explosion of lead nitroresorcinate suffered burns of the upper extremities and the thorax as well as foreign body lesions in both eyes. The bulbar conjunctiva and the lower temporal quadrant of the cornea of the right eye had numerous small grayish-white opacities in the epithelial layer. Vision was 6/6. The left eye also had numerous opacities in the exposed section of the conjunctiva. The cornea was dotted with numerous dust-like grayish-white incrustations which were confluent in places and also involved the parenchyma. The structure of the iris was blurred and somewhat hyperemic. The incrustations probably were lead oxide. Microanalysis of particles of the corneal

opacities by a spectrographic method failed to show lead. The author tried to dissolve the opacities which, in later stages, probably consist of lead carbonate, by application of ammonium tartrate.

F. Nelson.

Pendexter, S. E., Jr. **B. pyocyaneus corneal ulcer treated with penicillin.** Am. J. Ophth. 31:862-863, July, 1948.

Rössler, F. **Psoriasis of the conjunctiva.** Proc. Ophth. Soc. Vienna p. 42, Feb. 22, 1943.

A woman, 29 years of age, had generalized psoriasis on the face, forehead and upper and lower lids as well as on the trunk and limbs. The efflorescences of the lids continued into the conjunctiva where the lesion was variable and changed within a few days. The differentiation from seborrhoeic eczema is often difficult.

F. Nelson.

Rössler, F. **Clearing of a band-shaped corneal opacity.** Proc. Ophth. Soc. Vienna p. 42, February 22, 1943.

A 10-year-old child suffered from iridocyclitis for the last four years and developed a band-shaped corneal opacity. Rössler removed the epithelium of the cornea and treated the area with a two-percent hydrochloric acid solution. The corneal opacity cleared up immediately.

F. Nelson.

Sauer, H. **Treatment of herpetic corneal ulcers by cauterizing with zinc sulfate.** Proc. Ophth. Soc. Vienna p. 42, Feb. 22, 1943.

Since 1925 patients with herpetic eruptions of the cornea are treated with 20-percent zinc sulfate solution which is applied with an applicator after cocaine anesthesia. Immediately afterwards the eye is rinsed with physiologic saline solution and bandaged with collargol ointment. Usually an early lesion heals within three to five days after one cauterization, older and extensive lesions within 8 to 13 days. Only two recurrences were observed. Burning pains usually persist for several hours after the treatment. It is necessary to sterilize the zinc sulfate solution by boiling because molds grow readily in it.

UVEA, SYMPATHETIC DISEASE, AQUEOUS

Alagna, Gaspare. **More about the etiogenesis of recurrent uveitis with hypopyon.** Ann. di ottal. e clin. ocul. 73: 53-61, Jan., 1947.

A 52-year-old man had severe unilateral uveitis, in the course of which hypopyon occurred three times, and which was also accompanied by a typical dendritic keratitis. This and other cases which he has already reported support Alagna's thesis that the etiology of this very serious ocular syndrome is to be attributed to the virus of herpes simplex or at least to a herpetiform virus.

Harry K. Messenger.

Lindner, K. **Prevention of expulsive hemorrhage.** Proc. Ophth. Soc. Vienna, p. 62, Jan. 17, 1944.

In the right eye of a woman 52 years of age, iridencleisis was performed for chronic glaucoma. After the scleral incision the iris bulged forward immediately, and during incision of the iris liquified vitreous body began to pour out. The sclera was trephined at once in the temporal upper quadrant but little blood escaped. Ophthalmoscopy revealed a large choroidal protrusion in the lower nasal quadrant. Another trephining hole was put in that region after which quantities of blood escaped in intermittent pulsating spurts. After two weeks high choroidal detachment was still present but it disappeared completely within three months. Vision became 6/9 and tension remained below 30 mm. Hg.

F. Nelson.

Simonelli, Mario. **Uveo-meningeal syndrome following epidemic keratoconjunctivitis.** Giorn. ital. di oftal. 1:25-35, Jan.-Feb., 1948.

In a 32-year-old woman a uveo-meningeal syndrome appeared a few days after the onset of a typical epidemic keratoconjunctivitis. There was a neuritis as well as a perineuritis and in the absence of choroidal lesions the author attributes this to a direct transmission of the infection from the leptomeninges to the sheath of the optic nerve. All the lesions are believed to be the result of virus infection. The allergic mechanism is suggested as one method of extension.

Francis P. Guida.

9

GLAUCOMA AND OCULAR TENSION

Copps, L. A. **Cyclodialysis and iridectomy for glaucoma with cataract.** Wisconsin M. J. 47:469-471, May, 1948.

The author reviews the literature on the surgery of cataract occurring in eyes with glaucoma. His method of combined cyclodialysis through a scleral incision and iridectomy through a keratome incision at the limbus at the same operation has proved successful in five out of eight patients. These had advanced glaucoma. It seemed imperative to control the tension in one operation, a minimum of surgery was desirable, and in gonioscopic examination a large part of the chamber angle was found closed.

Harshman, J. P. **Glaucoma associated with subluxation of the lens in several members of a family.** Am. J. Ophth. 31: 833-836, July, 1948. (1 figure.)

Jacobs, C. H. **Cataract extractions under intravenous pentothal sodium anesthesia.** Pennsylvania M. J. 51:861-865, May, 1948.

The author reviews the literature and presents a report on 77 cataract extractions done under intravenous sodium pentothal anesthesia. In the postoperative course 77 percent were satisfactory, and 10 percent had emesis.

Orwyn H. Ellis.

Sautter, H. **Subcapsular collection of fluid in a shrinking traumatic cataract.** Klin. Monatsbl. f. Augenh. 112:316-318, 1947.

Two cases of traumatic cataract after perforating injuries are reported. The cortex and nucleus underwent shrinkage, but this shrinkage was not everywhere followed by the lens capsule. The latter formed a small, optically transparent sac above the shrunken cataract. The author assumes that fluid has collected within this space, either by secretion or by invasion from the aqueous. (3 references.)

Max Hirschfelder.

Simonelli, Mario. **The effect of the administration of nicotinic acid and its amide on the manifestations of napthalene cataract.** Giorn. ital. di oftal. 1:47-52, Jan.-Feb., 1948.

Previous investigations of the author have demonstrated that nicotinic acid normally present in the lens is greatly reduced in the cataractous lens. In this paper he demonstrates conclusively that nicotinic acid or its amide, administered subcutaneously or subconjunctivally does not interfere in any way with the production of the naphthalene cataract in the rabbit, but rather tends to accelerate the rate of its appearance. This is possibly caused by the vasodilating action of the PP factor, which increases the amount of the toxin in the aqueous, and a greater stimulation of the auto-oxidative processes of the lens. Francis P. Guida.

10

CRYSTALLINE LENS

Gittler, R. **Cataracta pisciformis.** Proc. Ophth. Soc. Vienna, p. 93, Feb. 26, 1945

A rare type of bilateral cataract was seen in the eyes of a man, 45 years of age, whose father, paternal aunt, and one of his sisters likewise had cataract. The lens opacities were flat and just anterior to the adult nucleus. In addition, small, dense, ring-shaped opacities, some of them with clear centers, could be seen in front of the flat opaque layer. The zone of the senile nucleus was much closer to the lens capsule in the central than in the peripheral area. This cataract resembles that which Vogt described as pisciform and is a hereditary congenital cataract. F. Nelson.

RETINA AND VITREOUS

Agnello, F. **Toxic amblyopia in a subject with an idiosyncrasy to quinine.** Riv. di ottal. 2:155-163, March-April, 1947.

The author discusses a case of toxic amaurosis, due to idiosyncrasy, in a young man who had ingested two grams of quinine. The ophthalmoscopic picture was the classic one of quinine poisoning: optic atrophy, thinning of retinal vessels and marked constriction of visual fields. The pathogenesis of the blindness is similar to that due to male fern and a result of the direct action of the drug on the sensory elements of the retina. The ischemia is secondary.

Francis P. Guida.

Appleby, R., and Pischel, D. K. **Review of 100 cases of retinal detachment.** Am. J. Ophth. 31:796-804, July, 1948. (1 figure, 4 tables, 10 references.)

Harwood, D. H. **Solar eclipse and vision.** Ann. Western Med. and Surg. 2: 22-223, May, 1948.

The author reports a case of macular damage that followed looking at an eclipse without proper protection. A program for prevention, especially publicity in schools, is outlined.

Orwyn H. Ellis.

Lewis, P. M. **Diathermy treatment of angioma of the retina.** Am. J. Ophth. 31: 829-833, July, 1948. (2 figures, 10 references.)

Mallner, J. **Macular hemorrhage in spotted typhus fever.** Proc. Ophth. Soc. Vienna, p. 82, Oct. 23, 1944.

A man, 38 years of age, had spotted typhus fever with all the typical symptoms. When he awoke after 10 days of deep stupor the vision of the right eye was blurred. A small, oval, dark-red hemorrhage with the surface of a raspberry was found in the macula. Vision gradually improved during absorption of the hemorrhage to 6/18. Macular hemorrhages are extremely rare in spotted typhus fever. F. Nelson.

Tower, Paul. **Solar retinitis.** Ann. Western Med. and Surg. 2:217-221, May, 1948.

The author reviews the literature and reports nine cases of central retinitis due to exposure during an eclipse. A plea is voiced for prevention through education of teachers and parents.

Orwyn H. Ellis.

12

OPTIC NERVE AND CHIASM

Barazzoni, Antonio. **Observations on cases of optic atrophy from methyl alcohol poisoning.** Ann. di ottal. e clin. ocul. 73:8-27, Jan., 1947.

The present-day knowledge of methyl alcohol poisoning is summarized with especial reference to toxicology, symptomatology, ocular lesions, pathologic anatomy, pathogenesis, diagnosis, and therapy. Six cases are presented, in all of which the vision was reduced and the nerve heads showed atrophy of the simple type. Various modes of treatment were tried, but in no case was there other than temporary recovery of vision.

According to the most plausible hypothesis the toxic substances reach the op-

tic nerve by way of the central retinal vessels and are rapidly absorbed by the tissues, where they come in contact with the papillomacular bundle and cause irritation but no true inflammation. The retinal ganglion cells participate in this irritative state and in consequence undergo irreversible degenerative changes because of which all therapy is unsuccessful.

Harry K. Messenger.

Esente, Ivan. **Optic neuritis due to lactation.** Giorn ital. di oftal. 1:53-72, Jan.-Feb., 1948.

The author reviews reported cases of optic neuritis during lactation and emphasizes the differentiation between optic neuritis during lactation and optic neuritis due to lactation. In the first group the etiology does not differ from that of any other neuritis. The second group is more definitely that of a metabolic neuritis most likely due to a poor utilization or to a true deficiency of vitamin B. Cessation of nursing usually allows a reestablishment of the vitamin equilibrium in a short time. The author describes one case in which vitamin B therapy brought about some improvement in vision.

Francis P. Guida.

Klein, R., and O'Mallie, P. P. **Chiasma lesion due to fall in epileptic fit.** Brit. M. J., pp. 880-881, May 8, 1948.

A 32-year-old male epileptic fell and struck his right forehead during a seizure. Blindness and optic atrophy occurred in the right eye, and a temporal field defect in the left. No fracture was found. The vision of the right eye improved to 6/9 seven months later but this did not remain long and blindness ensued. The visual field and acuity improved to normal in the left eye. The lesion was thought to be vascular, in or near the anterior chiasmal angle. (References.)

Bennett W. Muir.

Pickard, Ransom. **The alteration in size of the normal optic disc cup.** Brit. J. Ophth. 32:355-361, June, 1948.

The author presents a large series of patients observed over a fifteen-year period. A steady and regular increase in the size of the normal cup of the optic disc was noted. The cups did not average over one-half of the size of the disc. When a cup occupies 70 percent of the disc area further tests should be made before considering it normal.

NEURO-OPHTHALMOLOGY

Bender, M. B., and Brown, C. A. **The character of the nystagmus induced by amytal in chronic alcoholics.** Am. J. Ophth. 31:825-828, July, 1948.

Cholst, M. R. **Widening of the angioscotoma in the alarm reaction.** Am. J. Ophth. 31:821-825, July, 1948. (3 figures, 2 tables, 10 references.)

Cristini, Giuseppe. **Anomalous associated movements of lids and pupils from abnormal regeneration of oculomotor nerve fibers.** Riv. oto-neuro-oftal. 22:323-334, Sept.-Dec., 1947.

Three cases are reported showing some phenomena characterized by abnormal movements of lids and pupils due to anomalous regeneration of fibers of the third cranial nerve after trochlear paralysis. A boy of 15 years had paralysis of the

left third and fourth cranial nerves from a probable rupture of an aneurism of the circle of Willis. On looking downward or inward the left upper lid retracted upward; the left pupil at rest was larger than the right one, and it did not react in the usual tests, It became contracted on looking downward and inward. A woman, 40 years of age, after cranial trauma showed a limited movement of the right eye. At rest the left upper lid was higher than the right and on looking down it went still higher. The right pupil was dilated and rigid and the left did not react to light. A woman, 56 years of age, with persistent headaches from a probable aneurism of the circle of Willis had a right oculomotor paralysis. She exhibited the same type of upper lid and pupil anomalies as the other woman. The writer states that the sign of Fuchs is due either to an increased tonus of the lid elevator because of an anomalous regeneration of fibers to the elevator or due to transmission to this muscle of the impulses which normally go to the orbicularis. The pupillary associated movements are ascribed to an analogous regeneration of fibers. Similar phenomena are well known in neurology. They always suggest a trochlear lesion and may give a hint in the diagnosis of the site of the original lesion and the time when it occurred. (Bibliography.) Melchiore Lombardo.

Di Luca, Giuseppe. **A provoked retinal angiospasm.** Riv. oto-neuro-oftal. 22: 309-322, Sept.-Dec., 1947.

A woman, 50 years of age, with chronic simple glaucoma showed a rapid emptying of the retinal artery when her carotid sinus was compressed by a finger. The emptying took place from the center towards the periphery of the disc. As soon as the pressure was released the empty section of the artery refilled. During the compression the patient had difficult respiration, blurred vision, tremor and paresthesia of the limbs, and a threatened collapse. The writer concludes that the compression of the carotid provoked an angiospasm of the central retinal artery with angiospasm of the small cerebral arteries, cerebral ischemia and cardiac inhibition. The carotid sinus which regulates the general blood flow has no action on the arteries of the brains. A peripheral vasomotor neuro-vegetative center must exist common to ophthalmic territories. (Bibliography.)

Joy, H. H. **Agnostic alexia without agraphia following trauma.** Am. J. Ophth. 31:811-820, July, 1948. (3 figures, 35 references.)

Matteuci, P., and Kluzer, G. **The question of double cortical representation of the macula.** Riv. oto-neuro-oftal. 22: 253-262, July-Aug., 1947.

A man of 33 years had short attacks of headaches of sudden onset which then became continuous. At the same time ocular disturbances consisted of a marked defect of central vision in both eyes, a right lateral homonymous hemianopsia, with a bilateral central scotoma and marked papilledema in both eyes. A diagnosis of intracranial tumor was made and trephining of the occipital region at left showed the presence of a big meningioma occupying almost the entire left occipital lobe. It is noteworthy that a tumor localized in one occipital lobe could provoke not only the homonymous lateral hemianopsia but a bilateral central scotoma instead of a simple hemianopic scotoma. Clinical and experimental data do not give clear evidence of double cortical representation of the macula. Experimental researches do not show that macular crossed fibers exist. Individual variations in the localization and also a true unilateral cortical specialization of the central vision may exist. (Bibliography.)

Melchiore Lombardo.

NEWS ITEMS

Edited by DONALD J. LYLE, M.D.
601 Union Trust Building, Cincinnati 2
News items should reach the editor by the 12th of the month

DEATHS

Dr. Frederick William Adams, Carmel, California, died April 23, 1948, aged 88 years.

Dr. Emil Amberg, Detroit, Michigan, died April 12, 1948, aged 79 years.

Dr. William Rudisel Fringer, Rockford, Illinois, died March 7, 1948, aged 84 years.

Dr. William Elliott Gamble, Santa Monica, California, died April 23, 1948, aged 88 years.

Dr. William Burton Newton, Alpena, Michigan, died April 19, 1948, aged 67 years.

Dr. H. Lee Simpson, Detroit, Michigan, died February 3, 1948, aged 69 years.

Dr. Hiram Jason Smith, Chicago, Illinois, died February 16, 1948, aged 65 years.

MISCELLANEOUS

ENDOW OPHTHALMIC FELLOWSHIP

Alumnæ of the Upsilon chapter of the Delta Gamma sorority of Stanford University have presented the university with an endowment of $41,000 for a fellowship in ophthalmology. The gift represents proceeds of the sale of the sorority house following dissolution of Stanford sororities in 1944. Presentation of the gift, which fits into a national Delta Gamma alumnæ project for the care and prevention of blindness, followed approval by the superior court of Santa Clara County of the dissolution of the Stanford Delta Gamma association as a corporation. Sorority gifts also included a contribution to the building fund of the Palo Alto Society for the Blind.

SOCIETIES

CINCINNATI OPHTHALMOLOGICAL CLUB PROGRAM 1948-1949

The Cincinnati Ophthalmological Club announces its program for the coming year. Beginning in October, the club will meet on the second Friday evening of each month. The program will include as guest speakers: Dr. Herman M. Burian, Boston; Dr. Peter C. Kronfeld, Chicago; Dr. Alston Callahan, Birmingham; Dr. Derrick Vail, Chicago; Dr. Harold F. Scheie, Philadelphia.

Newly elected officers of the club for the year 1948-49 are: presidium, Dr. Donald J. Lyle, Dr. Ira A. Abrahamson, and Dr. Karl W. Ascher; secretary and treasurer, Dr. Joseph D. Weintraub; historian, Dr. Karl L. Stoll; program committee, Dr. K. W. Ascher, Dr. George Heidelman, Dr. Albert L. Brown, and Dr. Francis X. Siegel; committee on clinical presentations, Dr. Ira A. Abrahamson, Dr. Richard A. Hoffman, Dr. Barnet R. Sakler, and Dr. Cyril E. Schrimpf; dinner committee, Dr. Donald J. Lyle, Dr. Horace W. Reid, Dr. Victor Ray, Dr. Charles A. Hofling, and Dr. Louis J. Hendricks.

PERSONALS

HEADS CLEVELAND CLINIC

Dr. Roscoe J. Kennedy has been appointed head of the department of ophthalmology at the Cleveland Clinic. After receiving his medical degree, in 1931, at the University of Iowa College of Medicine, Dr. Kennedy interned at Harper Hospital, Detroit, and served as resident at the Buffalo (New York) General Hospital and at Wills Hospital, Philadelphia.

Dr. Kennedy came to the Cleveland Clinic in 1937 to complete a fellowship course of study and was appointed to the professional staff in 1938. During World War II, he served for four years in the medical corps of the U. S. Navy in the Southwest Pacific, holding the rank of captain.

Dr. Kennedy was certified by the American Board of Ophthalmology in 1939, and has made various contributions to medical journals. He is secretary-treasurer of the Cleveland Ophthalmological Club and is also a member of the Cleveland Academy of Medicine, American Medical Association, and American Academy of Ophthalmology and Otolaryngology. He was born at New Hampton, Iowa, and attended Notre Dame University.

WINS LITERARY PRIZE

At the exhibit of the American Physicians Literary Guild at the A.M.A. convention in Chicago, Dr. Joseph I. Pascal, New York, received first prize for his essay, "On Lecturing and Teaching."

APPOINTED PROFESSOR AT JEFFERSON

Dr. Arno Emerson Town, clinical professor of ophthalmology, New York University College of Medicine, has been appointed professor of ophthalmology at Jefferson Medical College to succeed Dr. Charles E. G. Shannon, who has retired. Dr. Town was graduated from Jefferson in 1926. He also received a Master of Medical Science degree in ophthalmology from the University of Pennsylvania School of Medicine in 1931. During the last war he served as a commander in the United States Naval Reserve as ophthalmologist at the United States Naval Medical Center, Bethesda, Maryland, and aboard the hospital ship *U. S. S. Benevolence.*

THE PROVOCATIVE TESTS IN THE DIAGNOSIS OF THE GLAUCOMAS*

H. SAUL SUGAR, M.D.
Detroit, Michigan

The importance of establishing the diagnosis in the early glaucomas has led to a long list of so-called provocative tests for these conditions. These tests attempt to cause an abnormal elevation of intraocular pressure as evidence of a disturbance in the regulatory mechanism of this pressure. However, with the increasing realization that we are dealing with several glaucomas rather than with a single disease entity, and because the provocative tests are generally considered unreliable,[1] an evaluation of several of these tests was undertaken in normal and glaucomatous eyes.

The various tests were made on the same group of glaucomatous patients so as to compare not only the test results with normal eyes, but also to compare the results of the various tests in the same glaucomatous eyes. As a consequence of these studies a further provocative test combination is presented which has given greater elevations of intraocular pressure than previously used tests.

The tests to be considered are the so-called water test, the caffeine test, the pupillary dilatation or mydriatic test, the combined cold-pressor and jugular compression test (the lability test), and a combination of the latter with the water test. These tests will be considered in the above order and then compared. All tonometric readings were made with a new Schiøtz tonometer, certified at the Chicago testing station, and are in terms of millimeters of mercury.

THE WATER TEST

The drinking test or water test was introduced by Schmidt[2] in 1928 following the studies of Marx[3] on the changes in the blood produced by drinking a liter of water.

METHOD

As the test is generally done, the patient drinks a liter of water before breakfast. Tonometric measurements are made every 15 minutes. In glaucomatous patients the tension is said to increase from 6 to 15 mm. Hg (Schiøtz) in about half an hour. In my own studies each test was done at least two hours after breakfast. Each patient was asked to drink a liter of water within a period of five minutes. The readings were made at one-half hour and again at one hour following the water ingestion.

RESULTS

In 143 normal eyes of adults from 18 to 70 years of age, the average rise of intraocular pressure was 1.9 mm. Hg (ranging from −2 to +9 mm.) at one-half hour. At the one-hour reading the intraocular pressure decreased an average of 0.5 mm. (ranging from −2 to +13 mm.) from the half-hour reading.

In 17 eyes the one-hour reading was higher than the half-hour reading, while it decreased in the remaining 126. In the same group of 143 normal eyes, the tonometric tension rose from 23 to 27 mm. to 30 mm. in

* From the Wayne University College of Medicine and the Glaucoma Clinic, Receiving Hospital, Detroit. Under a grant from the W. K. Kellogg Foundation.

TABLE 1

RESULTS OF THE WATER TEST IN GLAUCOMATOUS EYES

(The figures in parentheses indicate the range of change)

Initial Tension (mm. Hg [Schiøtz])	Simple Glaucoma

40–44													1	+10	−8			

6 eyes, to 31 mm. in 1, and to 32 mm. in 2.

In all instances where the tension in normal eyes rose to 30 mm. or above, both in this group and those normals to be discussed, the patients were asked to return for visual-field studies and a review of the tonometry and ophthalmoscopy. Two thirds of them were studied in this way and no evidence of glaucoma was found. Many of these and of those who did not return were in the age group between 18 and 35 years. Glaucoma simplex in such a proportion of unselected normals is not to be expected. The significance of these readings of 30 to 32 mm. will be considered in a later section of this paper.

The water tests on glaucomatous eyes were done both without miotics and following the use of pilocarpine in operated and unoperated eyes. The results are shown in Table 1.

Control study

A control study was made on the same general group of glaucomatous eyes. Sixty-one were unoperated eyes with simple glaucoma. They were divided into two groups, the first consisting of 56 eyes with an initial tension under 40 mm. Hg and 5 with 40 mm. or over.

Those with an initial tension under 40 mm. showed an average decrease of 0.7 mm. after one-half hour, and an additional average decrease of 0.4 mm. during the second half hour. The range of change was −7 to +5 mm. In the 5 eyes with an initial tension of 40 mm. or higher, there was an average increase of 1 mm. after one-half hour and an average of zero change during the second half hour. The range of change was −8 to +12 mm.

Fourteen operated eyes with simple glaucoma were observed as controls. There was no significant relation between the initial pressure and the change after one-half hour and after one hour. At the half-hour reading these eyes showed an average decrease of 0.7 mm. During the second half hour a further average decrease of 0.7 mm. occurred.

Controls on 4 quiescent narrow-angle-glaucoma eyes showed an average increase of 1.7 mm. at the half-hour reading, with no change during the second half hour.

In 3 eyes with glaucoma seondary to posterior lens dislocation, the control readings showed an average increase of 3 mm. at one-half hour (range −2 to +7 mm.), followed by an average decrease of 1.3 mm. during the second half hour (range −5 to +2 mm.).

Comments

In the normal series reported above, the provocative effect of the water test averaged only 1.9 mm. in the first half hour but individual instances showed up to 9 mm. of increase, which is higher than many of the provocative results in the glaucomatous eyes. Thus, it is impossible to draw a sharp line separating the normal from the glaucomatous in every instance. Arbitrarily, one might say that an increase in intraocular pressure of over 9 mm. at the half-hour reading may be considered a positive water test. A negative test would not indicate the absence of potential glaucoma in the broad definition of this term, nor does a positive test prove its presence with certainty.

The average one-hour readings of this test, when compared to the half-hour readings, show a general decrease of intraocular pressure. However, in 18 of the 112 (16 percent) unoperated eyes with simple glaucoma in which the test was performed without the previous use of miotics, and in 12 of the 87 (13 percent) following the use of pilocarpine, there was an increase in the intraocular pressure during the second half hour. This indicates the necessity of doing the one-hour reading, at least when the rise during the first half hour indicates a negative response.

A separation of the results of the water test in unoperated eyes of patients with simple glaucoma according to the initial tension readings indicates that the average ele-

vation of intraocular pressure following the ingestion of a liter of water depends to some extent on the level of the initial pressure. With increasing levels of initial tension, there is proportionately a greater increase in the pressure increment as is shown in Figure 1. The same is true when the tests are done in the same group of eyes following

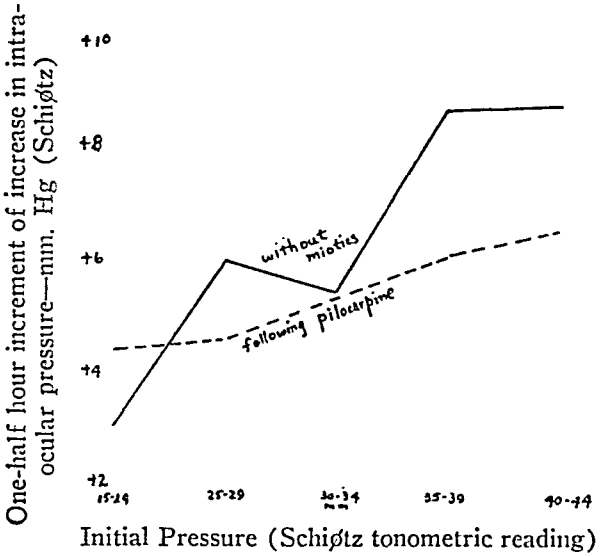

Fig. 1 (Sugar). The relation between the initial pressure and the increments of pressure increase at the half-hour readings of the water test in eyes with unoperated simple glaucoma.

the use of pilocarpine, although the increment of pressure rise is somewhat less (fig. 1).

Although the tested group of operated eyes with simple glaucoma and of eyes with the other glaucomas was too small for conclusions to be drawn, the water test caused a significant increase in intraocular pressure in some of them, in spite of an increase in the controls in the eyes with narrow-angle glaucoma and with glaucoma secondary to posterior lens dislocation. One should, therefore, be careful in using the water test as one of the differential criteria in separating the various glaucomas. It is probable that positive results with this test are not confined to eyes with simple glaucoma.

In the small number of successfully operated cases with well-filtering blebs, there was no significant difference in the rise in pressure produced by the water test in these eyes as compared to the tests on unoperated eyes with normal initial pressures. This suggests that the increase in pressure is too rapid to allow the blebs effectively to prevent it. It is evidence that the concept that these operations control but do not cure the glaucomatous process is correct.

The caffeine test

Lohlein[4] introduced this test which was originally carried out by giving an intravenous injection of 0.2 gm. of caffeine. Later, the test was carried out by having the patient drink 150 cc. of water containing 45 gm. of coffee. In the glaucomatous eye there is said to be a rise of up to 15 to 25 mm. Hg (Schiøtz) in 20 to 40 minutes. The use of black coffee has the disadvantage for investigative purposes that it introduces to some extent the factor of fluid volume involved in the water test.

Thirty-two unoperated eyes with simple glaucoma were studied using 0.5 gm. of caffeine sodium benzoate intramuscularly. The intraocular pressure was measured after a half hour, and again after one hour. All had initial tensions of less than 40 mm. Hg (Schiøtz). Twenty subjects were coffee drinkers while the remaining 12 used no coffee or tea. The coffee drinkers showed an average rise of 2.1 mm. (range —2 to +6 mm.) one-half hour after the caffeine injection and a subsequent average decrease of 0.1 mm. during the second half hour (range —9 to +7). The nonusers of caffeine-containing beverages showed an average decrease of 0.1 mm. at the half-hour reading (range —6 to +8 mm.) and a subsequent average rise of 0.5 mm. during the second half hour (range —6 to +3 mm.). These results did not indicate sufficient value to continue the investigation of caffeine by intramuscular injection as a provocative test.

The mydriasis test

The mydriasis test for glaucoma was used by Jackson[5] in the form of 2-percent cocaine, and with 2-percent euphthalmine by Gradle.[6] The tonometric readings were taken 90 to 120 minutes after the instillation. An increase of 7 mm. Hg or more (Schiøtz) was considered as evidence of a pathologic condition.

When the pupil is dilated there is an increase in the anteroposterior thickness of the iris at its root. In eyes with narrow angles, this leads to further narrowing of the entrance to the angle and may lead to partial or complete obstruction with resultant increased intraocular pressure. When the latter occurs, a definite relationship is found to exist between the chamber angle depth, the pupil size, and the thickness of the iris root.

In gonioscopic studies[7] of the effect of various mydriatic drugs on the fellow eyes of patients with unilateral acute glaucoma and on eyes which had suffered an acute episode but had become normal following the use of miotics, it was found that in each of the cases in which mydriasis caused an increase in intraocular pressure, the angle was open before pupillary dilatation, but closed by the iris at the end of dilatation. In the negative cases, the angle entrance remained open, although narrowed. The provocative dilatations were done with 2-percent euphthalmine, with 1-percent paredrine, or with 2-percent homatropine, and gave positive results in 7 of 20 eyes.

Method

In the present study, the pupils of 51 unoperated eyes with simple glaucoma were dilated with 4-percent homatropine hydrobromide, and the pupils of 49 eyes, nearly all of them the fellow eyes of those dilated with homatropine, were dilated with 10-percent neosynephrine. The initial tonometric readings were under 40 mm. Hg Schiøtz in these cases. No miotics had been used on the morning of the test. The tension observations and pupillary measurements were made a half hour and one hour after the instillations.

Results

The average rise in intraocular pressure in the homatropine group after a half hour was 0.5 mm. Hg (range −4 to +8 mm.), with another 0.5 mm. increase during the second half hour (range −4 to +6). In the eyes in which neosynephrine was instilled, there was an average fall of 1.7 mm. during the first half hour (range −8 to +7 mm.), with an average recovery of 0.2 mm. during the second half hour (range −6 to +8). The pupils dilated on the average 1 to 2 mm. more with neosynephrine than with homatropine but dilated well. There was no instance of an increase of intraocular pressure of over 8 mm. in any case of simple glaucoma. No instance of congestive reaction occurred even though the patients were permitted to leave the clinic while the pupils were still dilated.

In contrast to the above findings were the results in 7 quiescent eyes which had either had acute glaucomatous attacks with congestion previously or were the fellows of such eyes. The pupils of the remaining 3 were dilated with 10-percent neosynephrine. In one eye of the homatropine group neosynephrine was later used for the mydriasis test.

Of the 4 homatropinized eyes, 2 showed no rise in tension, while 2 showed significant increase, one from 29 to 70 mm. Hg in one-half hour; the second, from 25 to 41 mm. Hg in one hour. Of the eyes in which neosynephrin was used, 2 showed no rise in pressure, and 2 showed significant increase, one from 38 to 70 mm. Hg in one-half hour, and the second showed no rise during the first 5 hours but during the 6th hour tension rose from 22 to 51 mm.

Comment

In 1941, as the result of the previously mentioned gonioscopic studies, I pointed out[8] that the provocative tests for glaucoma may be divided into two groups, one group for eyes with normal anterior-chamber depth, including the caffeine test, the water test, and anterior-chamber puncture in the order named (these tests no longer have the same significance, as indicated elsewhere in the paper), and a second group with shallow chambers and narrow angles for which the mydriatic tests were indicated.

It appeared then, as it does now, that as a provocative test pupillary dilatation can be of various degrees, from mere discontinuance of miotic medication in a controlled narrow-angle glaucoma patient with very shallow chambers, to the next degree—the darkroom test, and then the use of weaker and then stronger mydriatic drugs. Only when adequate pupillary dilatation has been obtained is the mydriatic test of any value.

Additional factors should be considered. The first is the time factor which is required for dilatation and the building up of tension. In my experience, once the angle is blocked, the pressure rises within 20 to 30 minutes to high levels. Patients provoked with mydriatic drugs should be observed for about 4 to 5 hours before considering the test negative. There should be no hesitancy in using any of the mydriatic drugs except scopolamine and atropine for these tests, since the other mydriatics can be counteracted without too much difficulty.

Another factor in using mydriatic drugs is that some of the drugs, especially the spastic mydriatics, are also vasoconstrictors. The latter action tends to thin the iris while it dilates, so that these drugs require greater dilatation to get angle blockage than do drugs like homatropine.

The findings of the present study reiterate the lack of danger of mydriasis in simple glaucoma, and its danger in narrow-angle glaucoma. No mydriatic is free of danger in preacute glaucomatous eyes.

The pressor-congestion test

The pressor-congestion test, the so-called lability test of Bloomfield and Lambert,[9] was presented by these two investigators in 1945. It was based on a combination of the cold pressor test of Hines and Brown[10] which is a vasopressor reaction of probable neurogenic origin and the jugular compression test of Wessely and Schoenberg.[11]

Method

The pressor-congestion test is performed in the following manner: An initial tonometric reading is made with the patient lying supine. A sphygmomanometer cuff is placed loosely about his neck with the rubber portion anteriorly, over the jugulars. One of the patient's hands is immersed to the wrists in chipped ice and water and the cervical cuff inflated to between 50 and 60 mm. of mercury for one minute. A tonometric reading is then made and the hand removed from the ice water, and the cervical cuff deflated. The tension returns to the level of the initial reading almost immediately.

In the pressor-congestion tests made in this study the rubber portion of the cuff was folded and taped in this position to make it narrower before applying it to the neck.

Results

In 192 normal eyes, this test gave an average increase of 3.6 mm. Hg (Schiøtz) (range −2 to +9 mm.). Only 6 showed a decrease of up to 2 mm. Of the 192 eyes, 39 (20.3 percent) showed a rise of intraocular pressure from an initial reading of 23 to 28 mm. to up to 33 mm. as follows: 18 increased to 30 mm., 5 to 31 mm., 9 to 32 mm., and 7 to 33 mm.

The pressor-congestion test was performed in 112 unoperated eyes with simple

glaucoma and 13 operated ones as well as in 4 unoperated eyes with narrow angles and a history of previous acute glaucoma. The results are shown in Table 2.

Comments

According to Bloomfield and Lambert,[9] the most important factors in determining the intraocular pressure at any time are the variations in the volume of the intraocular fluids. This volume depends on the blood flow, so the transient vascular congestion induced by the pressor-congestion test tends to produce an increase in intraocular pressure which is particularly evident when the mechanisms controlling the intraocular pressure are defective.

There is one mechanism which has not been considered by Bloomfield and Lambert in the transient rise of intraocular pressure produced by the pressor-congestion test. This is the effect on the extraocular musculature. Any test such as the one under consideration, whereby the tonus of the extraocular muscles as well as the tonus of all the voluntary muscles is increased, would cause an increase in intraocular pressure. I am under the impression that those patients who are most tense under the conditions of the test have a greater increase in intraocular pressure.

Bloomfield and Lambert claimed that if this procedure produced a rise in ocular tension of over 9 mm. the diagnosis of chronic simple glaucoma was strongly suggested and, if the height to which the tension rose in the tested eye exceeded the normal limit of 30 mm., whether or not the actual rise in tension was more than 9 mm., such a diagnosis was even more conclusively indicated. In the glaucomatous eyes of my series the rise of intraocular pressure from application of the pressor-congestion test did not exceed the 9 mm. level mentioned by Bloomfield and Lambert in even half of the cases.

In the normal series of eyes, the occurrence of an increase of intraocular pressure to 30 mm. or above in 20 percent of the eyes does not agree with the second portion of the above claim.

Four patients of the normals who showed an increase in tension to 30 mm. or above with the pressor-congestion test were subjected to anterior-chamber puncture. All gave responses which I consider normal. The results are shown in Table 3. In each case there was no evidence of leakage from the puncture wound as shown by the application of fluorescein. A single control puncture in an eye with definite early simple glaucoma, with an initial tension of 26 mm. and a rise to 35 mm. following the pressor-congestion test, was followed by a rise to 56 mm. at the 2-hour reading, a definitely glaucomatous response.

The anterior-chamber puncture test[12] in

3.	26 mm.	32 mm.	32 mm.
4.	28 mm.	32 mm.	33 mm.

my experience is an excellent test for simple glaucoma and one which is useful in investigative work, although in office practice and even in the clinic rarely is indicated. It is not without danger, and should not be repeated too often with total evacuation of the aqueous as it may lead to stretching of the zonule.

In this test a normal response may be considered to be anywhere in the low 30's. I see no reason why a provocative rise in intraocular pressure to 30 mm. or above in normal eyes may not occur with the water and pressor-congestion tests as it does in the chamber puncture test.

THE WATER AND PRESSOR-CONGESTION TEST

METHOD

In order to increase the strain on the regulatory mechanism of the ocular tension, in line with the idea of the pressor-congestion test, a combination of the water test and the pressor-congestion test was studied in 71 normal eyes and in 107 glaucomatous eyes. This test was started at least two hours after breakfast or lunch. An initial tension reading was made and the patient given a liter of water to drink within a period of about five minutes. At the end of a half hour, the pressor-congestion test was done. The difference in tension between the initial reading and that at the end of the pressor-congestion portion of the test was recorded.

RESULTS

In 71 normal eyes the average rise in intraocular pressure after this test was 5 mm. (range −3 to +10). Of these, 24 (33.8 percent) rose from a normal of 23 to 28 mm. to 30 mm. or over, as follows: 10 increased to 30 mm., 6 to 32 mm., 2 to 33 mm., 3 to 36 mm., and 3 to 38 mm.

The results of the combined test in glaucomatous eyes are shown in Table 4. They indicate a greater increase is tension with this test than in any of the previous ones. A comparison of the results of the water test, the pressor-congestion test, and the combined test shows these results more clearly. In Table 5 are shown the compared results in normal eyes and in Table 6 those in glaucomatous eyes.

Further comparison of the tests was made by doing the various tests at different times in the same eyes. In normal eyes a comparison of the water test with the pressor-

40–44	5	+17	+7 to +29	2	+ 8.5	+ 7, +10			

TABLE 5

A COMPARISON OF THE WATER, PRESSOR-CONGESTION, AND COMBINED TESTS IN NORMAL EYES

	Number of Eyes	Average Increase in Tension	Range	% of Increase to 30 mm. or Above
		mm.	*mm.*	
Water test	143	½ hr. +1.9 1 hr. −0.5	−2 to + 9	6.3%
Pressor-congestion test	192	+3.6	−2 to + 9	20.3%
Combined water and pressor-congestion test	71	+5.0	−3 to +10	33.8%

congestion test was made in 38 eyes. The water test gave an average increase of 2.5 mm. in a half hour, followed by an average decrease of 0.8 mm. during the second half hour. The pressor-congestion test in these same eyes gave an average increase of 3.3 mm.

A further comparison of the water test and the combined water and pressor-congestion test was made in 27 normal eyes. In the water test, there was an average increase of 2.8 mm. in a half hour and an average decrease of 0.8 mm. during the second half hour.

The eyes on which the combined test was done had tonometric readings both before and after the pressor-congestion portion of the test. The reading after the water portion and just before the pressor-congestion portion indicated an average increase of 2.8 mm. At the end of the pressor-congestion portion it had risen an additional average of 2.2 mm., a total of 5.0 mm. for the test.

TABLE 6

A COMPARISON OF THE AVERAGE INCREASE IN TENSION PRODUCED BY THE WATER, PRESSOR-CONGESTION, AND COMBINED TESTS IN UNOPERATED SIMPLE GLAUCOMATOUS EYES

Initial Tension (mm. Hg [Schiøtz])	Water Test (no drops) ½ hr.	Pressor-congestion Test	Water and Pressor-congestion Test
	mm.	*mm.*	*mm.*
15–24	+2.9	+7.1	+ 9.7
25–29	+5.9	+4.2	+ 8.3
30–34	+5.4	+4.3	+11.5
35–39	+8.7	+2.9	+ 7.9
40–44	+8.2	+8.2	+17.0

All three tests were made at different times on the same group of 81 unoperated and 10 operated eyes with simple glaucoma. The initial tensions were under 40 mm. Hg (Schiøtz). A comparison of the results is shown in Table 7.

COMMENTS

It is apparent, in comparing the three tests, that the average tension rise is greater in the pressor-congestion test than in the water test, and highest of all in the combined test but that there is also a proportional increase in the number of normals rising to 30 mm. or above.

Since the range of tension rise in the normal eyes studied with the combined test was practically the same as with the other two tests, one would be justified in saying that an increase of over 10 mm. indicates a positive test. However, most of the glaucomatous eyes showed lesser increases than this. As with the other provocative tests, a negative result does not rule out glaucoma.

TABLE 7

A COMPARISON OF THE WATER, PRESSOR-CONGESTION, AND COMBINED TESTS IN THE SAME SERIES OF EYES WITH SIMPLE GLAUCOMA

	Average Rise in Tension in mm. Hg (Schiøtz)	
	Unoperated	Operated
Water test		
½ hr.	+5.6	+6.0
1 hr.	−2.1	−2.0
Pressor-congestion-test	+4.8	+6.5
Water and pressor-congestion test	+8.9	+8.8

Conclusions

The combined water and pressor-congestion test gives evidence of higher responses in glaucoma than do the water or pressor-congestion tests alone.

With the water test, a positive result may be considered to be a rise of over 9 mm. or a rise to over 32 mm. With the pressor-congestion test, a rise of over 9 mm. or a rise to over 33 mm. may be considered a positive result. With the combined test, a positive test may be considered to be a rise of over 10 mm. or to over 38 mm. Unless the ceilings mentioned above are used, there is danger of diagnosing glaucoma in normal eyes.

The caffeine test, as performed in this study, gives no consistent results.

Mydriasis in simple glaucoma is harmless and has not given a single significant increase in pressure. In eyes with narrow angles, it is the best available provocative test but is dangerous if not adequately followed by miotics. Although the vasoconstricting spastic mydriatics are relatively less dangerous than the others, they do cause angle blockage in some cases. No mydriatic is without danger in such eyes.

No provocative test is of greater diagnostic value than the practice of routine and repeated tonometry in all patients 40 years of age or older, especially in early simple glaucoma where no field changes have occurred, and where the tension is at the borderline of normal. In a minority of instances these tests will give some aid in diagnosis.

1108 Stroh Building (26).

The author wishes to acknowledge the kind aid of the following in his work with the provocative tests: Dr. Benjamin Lyons, Dr. Peter Petravice, Dr. Leonard Fox, and Dr. Lawrence Stocker.

THE PRESSOR TEST FOR GLAUCOMA*

GEORGE T. STINE, M.D.
St. Louis, Missouri

This study was undertaken in an attempt to confirm the lability pressor test for chronic simple glaucoma described by Bloomfield and Lambert.[4] The test was found to be not only quick and easy to perform, but was without question the most reliable test yet proposed for the diagnosis of one type of glaucoma. It was, however, found to be distinctly unreliable in another type of glaucoma.

THE PRESSOR TEST

Probably the most potent factor determining the intraocular pressure at any given time is the distensible vascular network of the globe. This vascular bed is under both nervous and hormonal control the same as any other vascular bed in the body. While the eye's capillary bed is not the sole regulatory mechanism of the intraocular pressure, it is probably the one subject to the most variations from time to time.

Although it is obvious that there are many other factors present in the control of intraocular pressure, the pressor test attempts to utilize the vascular variations within the semirigid coat of the globe to detect the presence of abnormal variations in the intraocular pressure.

As many authors have stated, the increased lability of the intraocular pressure is one of the most reliable signs of incipient glaucoma, and the test herein described is a method whereby a sudden strain is thrown on the regulatory mechanism of the eye so that increased lability will be made clinically appreciable.

Bloomfield and Lambert[4] state that, "The idea of a test to indicate the increased lability of [the intraocular pressure] is not new. In cases of diabetes mellitus and of vascular hypertension, for example, evidence of an increased lability in the regulation of levels of the blood sugar and the blood pressure, as indicated by the dextrose tolerance and the cold pressor test respectively, is considered a valuable indication of impending morbidity. The basic idea in such tests is to throw a sudden strain on [the control system] by means of a standardized stimulus and to record quantitatively the degree of deviation that occurs and the time necessary for the restoration of the physiologic norm."

With this idea in mind Bloomfield and Lambert[4] attempted to find some method whereby the flow of blood into the eye could be increased and the outflow decreased, thereby throwing a sudden strain upon the regulatory mechanism of the eye.

Hines and Brown,[6] in 1933 and 1936, described their cold pressor test, whereby sudden elevations of blood pressure, ranging from 10 mm. Hg rise in diastolic and systolic pressures up to approximately 40 mm. Hg rise in both diastolic and systolic pressures, could be obtained by the immersion of some part of the body in ice water. The amount of the rise was dependent up the vascular lability of the patient, *but there was some degree of rise found constantly in all persons!*

Wessely, Schultz, Thiel, and Schoenberg all wrote of the effects of venous congestion upon the intraocular pressure. Therefore, following the Schoenberg line of thinking, Bloomfield and Lambert used a blood-pressure cuff, applied so as to make jugular compression, in order to interfere with the drainage of fluid from the eye. By combining the cold pressor test with jugular compression, they then had a means whereby the flow of blood into the eye could be increased and at the same time the flow of blood out of the eye decreased. This forms the basis of the pressor test. For a complete history and background of the test the reader is referred

* From the Department of Ophthalmology, Washington University School of Medicine, and the Oscar Johnson Institute.

to the excellent descriptions by the original authors.[4]

Technique

The technique used in this test is briefly as follows: The patient is seated in a reclining treatment chair at about 30 degrees from the horizontal. A sphygmomanometer cuff is loosely applied to the neck so that the balloon is in front making pressure on the jugular veins. Pontocaine (½ percent) is instilled into the eyes and the tension measured with a regular Schiøtz tonometer. The patient is then fully instructed as to the procedure of the test. Following this, the hand and wrist of the patient are immersed in water that has previously been cooled to a temperature of approximately 4°C. Simultaneously, the sphygmomanometer cuff is inflated to a pressure of 50 to 60 mm. Hg and held there during the period of the test. At the end of one minute the ocular tension is taken while the patient still has his hand in ice water and the cervical compression is maintained. The ice water is then removed and the cuff deflated.

Subjects

For the purpose of this study, the patients selected were divided into two groups. One group, in so far as it was possible to determine, had no indications of abnormal intraocular pressure, while the other group consisted of patients with proven cases of glaucoma.

The patients in the latter group all had classical findings of glaucoma; that is, cupping of the discs, increased intraocular pressure measured on numerous occasions, and field changes compatible with glaucoma. Most of them had had other types of provocative tests as well. An attempt was made to exclude all inflammatory or postinflammatory types of glaucoma.

Early in the study no attempt was made to separate the wide-angle from the narrow-angle types of glaucoma, but it was soon noted that *there was a difference in the response to the test of these two types,* and so the two were separated. An attempt was made to find and test narrow-angle types of glaucoma for the purpose of this series and so the distribution of the wide-angle and narrow-angle types is not that normally found in a group of glaucomatous patients selected at random.

The "normal" group was made up of 35 eyes (19 patients), while the "glaucomatous" group was made up of 44 eyes (24 patients). The ages ranged from 21 to 82 years with a mean of 59.5 years for the normal group, and 62.7 years for the glaucomatous group. There were 14 males and 21 females in the normal group, and 16 males and 39 females in the glaucomatous group.

Results

The results of testing these groups revealed that first of all the test is highly dependable for the detection of early chronic simple glaucoma of the wide-angle type. However, several pitfalls were revealed that must be taken into consideration in the routine use of the test.

A statistical study of the results by the method of the analysis of variance revealed that the possibility of their being obtained by chance was less than one in a thousand ($p = .001$), which means that the results are highly significant.

It will be noted in Table 1 that the mean rise in pressure with the pressor test in the normal group was 1.94 mm. Hg. This may be compared with the mean rise in the intraocular pressure of 13.82 mm. Hg in the group of wide-angle glaucoma. The mean rise of intraocular pressure with the pressor test of the narrow-angle group of glaucoma was only 2.9 mm. Hg.

When the method of analysis of variance is applied to only these two selected groups, that is, the narrow-angle group versus the normal group, p is greater than .05. This means that such a small difference could easily have arisen on the basis of chance, and, therefore, the nil hypothesis—that there

is no difference between the means other than that due to sampling variation—would have to be considered true in so far as these groups are concerned. Some of the reasons for this variation will be discussed later. The fact that the pressor test reveals no significant rise in patients with narrow-angle glaucoma means that such cases *could not be detected with this test alone!*

Another very important consideration of any test is its validity. Here again, the pressor test stands up very well, in fact far above the results of other tests, with the possible exception of the water-drinking test of Marx. Bloomfield and Kellerman[3] used the pressor test in 34 known cases of glaucoma and had 31 positives and 3 doubtfuls. Inasmuch as they apparently did not correlate their results with the gonioscopic findings, this small percentage of missed cases may well represent narrow-angle cases. In the present series of 35 known wide-angle glaucomatous eyes the pressor test was positive in every case (table 1).

It should be noted here that the criteria used for a positive test were: (1) a rise of greater than 9 mm. Hg and/or (2) a rise to a ceiling level of more than 30 mm. Hg.

Mean rise in IOP		13.82			2.85			1.94
Mean ceiling pressure		36.0			18.25			18.45

Bloomfield and Lambert[4,2] felt that the latter was the more reliable of the two. One must agree with them, but it should be reëmphasized that the rise of 9 mm. Hg should not be overlooked. In this series there were only four cases whose tension failed to rise above

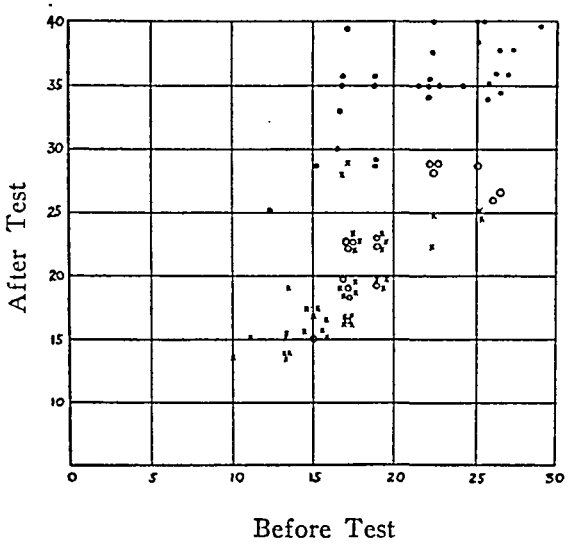

Fig. 1 (Stine). Effect of the pressor test on intraocular pressure. • = Wide-angle glaucoma. O = Narrow-angle glaucoma. × = Normal.

30 mm. Hg following the test. Case 44 showed a rise of 10 mm.; Case 55, a rise of 12 mm.; while Case 63 and Case 64 each showed a rise of 10 mm. Hg.

The mean ceiling of the wide-angle group of glaucomas was 36 mm. Hg, while that of the narrow-angle group was only 18.25 mm. Hg. The ceiling of the normal group was 18.45 mm. Hg.

Figure 1 is a scattergraph showing the correlation between the three groups being tested in this study when the pressure before test is plotted against the pressure after the test. It will be noted that the plotted points of the cases of narrow-angle glaucoma are practically superimposed upon those of the normal cases. This is in sharp contradistinction to the grouping of the wide-angle group. This scattergraph graphically illustrates the facts brought out by the numerical tabulation of the results, that narrow-angle glaucoma cases respond to the pressor test in the same manner as does a normal individual.

Bloomfield and Kellerman[3] tested 77 normal eyes with this test and had only one positive. This series shows 35 normal eyes and likewise one positive which was apparently a false positive in the sense that no signs of glaucoma were present at that time If we combine the two series, we get a total of 112 known normal eyes in persons subjected to the test and only two false positives. The misclassifications amounted to 1.7 per cent.

An analysis of the group with narrow-angle glaucoma showed that the mean rise in tension with the test was only 2.9 mm. Hg. The ceiling levels reached did not vary significantly from the normals. These cases were all proven to have glaucoma, however, by the presence of typical field changes, fundus pictures, and a positive provocative test with mydriasis. *These cases would have all been missed if reliance had been placed solely on the pressor test!*

A total of 82 eyes were subjected to mydriasis. Of these there were 33 with wide-angle glaucoma, 18 with narrow-angle glaucoma, and 31 normal eyes. Of the latter group, 5 had what would be classed as narrow angles.

TABLE 2

COMPARISON OF THE EFFECT OF PAREDRINE AND EUPHTHALMINE DILATION UPON THE INTRAOCULAR PRESSURE

Case No.	Initial Press.	Paredrine Dilation Pupil Size	Paredrine Dilation Final Press.	Euphthalmine Dilation Pupil Size	Euphthalmine Dilation Final Press.
6	17	6 mm.	22	7.0 mm.	35
13	17	7.5 mm.	19	8.0 mm.	29
17	19	7.0 mm.	22	7.0 mm.	28
88	22	7.0 mm.	25	8.0 mm.	35

From an examination of Table 3 it will be seen that the rise in pressure with mydriasis in the normal group was less than 1 mm. Hg, while the mean rise in the narrow-angle group was 14.33 mm. Hg. This should be contrasted with the mean rise of 3.69 mm. Hg in the wide-angle group of glaucomas with mydriasis.

In this study the mydriatics used were 2-percent or 5-percent homatropine, 5-percent euphthalmine, or 4-percent cocaine and 5-percent euphthalmine. Paredrine and neosynephrin were not included in this study because it was believed that their vasoconstrictive effects would often overbalance the mydriatic effect and thus introduce another variable.

It has been noted by other observers that paredrine is probably the safest of the mydriatics to use in the routine dilation of patients' eyes because it so infrequently causes a rise in intraocular pressure. Several of the eyes included in this study were dilated widely with paredrine with no appreciable effect upon the intraocular pressure; whereas, with euphthalmine and the same amount

of dilation, there was a significant rise in pressure (table 2).

In this study the effect of mydriasis was studied by measuring the intraocular pressure before the installation of a mydriatic and then again at least every hour until it ceased rising. This procedure was followed in all the cases except the eyes with narrow-angle glaucoma, in which a miotic was instilled after it was found that a significant rise had occurred.

From Table 3 it will be seen that every case classed as narrow-angle glaucoma in this series gave a positive mydriatic test using as a criterion the commonly accepted figure of a rise of more than 6 mm. Hg. In the 33 eyes with wide-angle glaucoma only 4 showed a significant rise in tension under the influence of mydriatics. (See discussion of these cases later.)

Discussion

An examination of the above results suggest several important facts and possible clues to some of the factors in the production of the glaucomatous state. The pressor test of Bloomfield and Lambert has been confirmed as a valuable diagnostic procedure in the study of glaucoma. It now seems obvious that the test is highly reliable in detecting chronic simple glaucoma of the wide-angle type, but almost useless in detecting narrow-angle glaucoma, a point not brought out by their work. However, several side issues were raised which, upon investigation, may be of distinct importance.

It would appear from the results of this study that there are two distinct mechanisms operating in the production of wide-angle glaucoma as opposed to narrow-angle glaucoma. This is not a new idea and has been proposed by Barkan,[1] Kronfeld,[7,8] Sugar,[9] and others. There is not complete acceptance of the idea, however, since Troncoso[10] in his recent book, *Gonioscopy,* says, "At this time a warning should be sounded not to believe that the mechanical application of the iris base against the cornea is the cause, the *primum movens,* of the development of acute or subacute attacks of glaucoma. Narrowing of the angle is only a predisposing factor as will be explained later."

Kronfeld and others[7] studied the effect of mydriasis in patients with wide-angle glaucoma and came to the conclusion that the intraocular pressure is not grossly influenced by the administration of mydriatics. They did, however, elicit a small rise. This was confirmed in this study, where the mean rise in intraocular pressure in the normal group was only 0.5 mm. Hg, as contrasted with the mean rise of 3.69 mm. Hg in the group of wide-angle glaucoma.

It will be noted that in four eyes the intraocular pressure rose precipitously with mydriasis, but fell promptly with miosis. These cases were included in this group because it was felt from clinical course and examination that, although the angles were narrow with many anterior peripheral synechias, the primary etiology of the glaucoma was that of a disturbance of the trabeculum—canal of Schlemm—mechanism typical of the wide-angle glaucoma. It is believed that the rise in tension with mydriasis was due to the narrowness of the angle and the anterior peripheral synechias, making it possible for the iris base to block the angle.

The fact that in this study all of the eyes with wide-angle glaucoma responded with a significant rise in intraocular pressure to the pressor test, while the group of narrow-angle glaucoma responded with a rise not significantly different from that of the normals, seems to indicate that there is an entirely different mechanism operating in the production of the glaucomatous state in the two conditions.

The pressor test is a method of throwing a sudden strain upon the reserve capacity of the pressure-regulating mechanism of the eye, acting through the vascular bed, which is thought to be the effector organ of the pressure-regulating mechanism.

Inasmuch as there is no angle-crowding effect resulting from this test, it seems to in-

dicate definitely that the etiology of the glaucoma in the wide-angle type of glaucoma is due to some pathologic condition in the drainage mechanism in the trabeculum and canal of Schlemm, and not directly related to the base of the iris.

Friedenwald[5] has demonstrated that with a rise of 5 to 10 mm. Hg in intraocular pressure, the rate of outflow of the aqueous is more than doubled. It then stabilizes on the "Friedenwald plateau" where a rise in pressure up to about 30 mm. Hg does not increase the rate of outflow. He interpreted this initial rise as a reserve of safety in the pressure-regulating mechanism, and thought that normal eyes maintain their intraocular pressure by staying within the limits of the plateau. However, in a glaucomatous eye that has no such margin of safety, any sudden strain upon the outflow mechanism would lead to an increase in the intraocular pressure. This is the elevation that is being measured by the pressor test.

On the other hand, the fact that the group with narrow-angle glaucoma did not respond by a rise in pressure with the test would make it appear that the filtration mechanism of the trabeculum and canal of Schlemm is functioning normally or at least almost normally in this latter type of case. These cases did respond with a rapid and significant rise coincident with mydriasis, the rise occurring presumably as soon as the pupil had dilated sufficiently to crowd or even partially block the angle.

Such patients, when examined with the gonioscope while the intraocular pressure was elevated, showed that the angle which had been narrow before was now almost invariably completely closed with the iris in apposition to the cornea or sclera. When a miotic was instilled and the pupil began to contract, reëxamination with the gonioscope revealed the previously crowded angle to be opening and the pressure soon fell rapidly to its previous level.

This evidence seems too conclusive to be denied and appears to be a powerful supporting girder in the structure of the "iris-block" mechanism built up by Barkan,[1] Kronfeld,[7, 8] Sugar,[9] and others. It certainly must be admitted, however, that there are eyes that at the time of examination show a narrow angle and yet have normal tensions and no other evidence of glaucoma, but there is no assurance that these same eyes will not develop narrow-angle glaucoma sometime in the future.

Another fact brought to light by this investigation was a probable correlation be-

TABLE 4

SHOWING THE CORRELATION BETWEEN A POSITIVE PRESSOR TEST WHILE ON MIOTICS AND THE VISUAL-FIELD LOSS

Case No.	Tension Range on Miotics	Pressor Test on Miotics	Pressor Test no Miotic	Visual Fields
4	17–22	19 to 22	27 to 38	No loss for six months
7	15–24	17 to 24	22 to 34	No loss for two years
8	17–22	19 to 29	19 to 35	Steadily progressive loss
9	15–25	17 to 22	30 to 40	No appreciable loss for two years
10	19–25	19 to 25	40 to 56	Very slight loss over period of two years
21	15–27	17 to 35	17 to 37	Progressive loss
22	19–25	22 to 35	22 to 35	Progressive loss, central and peripheral
51	13–22	15 to 17	26 to 35	No loss over period of six months
67	17–28	19 to 35	25 to 40	Slow progressive loss past ten years
68	15–22	15 to 25	17 to 30	Slight, but definite loss, ten years
90	19–25	25 to 29	26 to 35	No significant loss for past year
91	19–28	25 to 35	30 to 40	Definite central and peripheral loss
93	17–22	22 to 25	22 to 40	No loss
98	15–25	19 to 35	22 to 37	Steady loss of peripheral field

tween a positive pressor test in eyes under the influence of miotics and the amount of visual field loss. Bloomfield and Lambert[4] in their paper noted that patients under the influence of pilocarpine did not show the expected rise in tension with the pressor test. This fact was confirmed early in the present study.

Subsequent investigation revealed that these patients who had a positive pressor test *despite normal tensions under miotics* were all gradually losing visual field and visual acuity and were, therefore, not really controlled. On the other hand, those patients that had a negative pressor test while under the influence of miotics had been without appreciable field loss for a considerable time. This series is illustrated in Table 4.

It will be seen that of 14 eyes, 7 had had a progressive field loss despite the fact that the tension had always been noted to be well within the so-called normal zone. The tension in the other seven eyes stayed essentially within the same range, but these eyes had sustained no significant visual-field loss over a rather lengthy period of observation. In every case where there had been progressive field loss, the pressor test was positive while the patient was on his usual miotic regime and, conversely, the pressor test was negative in those patients that did not show a progressive loss of the visual fields.

The small number of cases certainly does not entitle one to draw any very valid conclusions as to the prognostic value of the pressor test, but does provide a clue that is being investigated further in an attempt to establish the pressor test as a prognostic procedure which will enable the clinician to foretell what course a given case of glaucoma may take on conservative therapy.

Summary

The pressor test was found to be a safe, easily performed test for the detection of chronic simple glaucoma of the wide-angle type. It was found to be completely unreliable for the detection of glaucoma of the narrow-angle type. Therefore, it is recommended that the test be used only in conjunction with the gonioscopic examination when there is any question of its validity.

Mydriasis was found to be a very reliable provocative test for the detection of narrow-angle glaucoma, but, contrary to popular belief, had practically no effect on the intraocular pressure in the wide-angle type of glaucoma.

The response to the pressor test and mydriasis of the two types of glaucoma suggests that there are entirely different mechanisms operating in their etiology.

The pressor test may, by further investigation, be found to have very definite prognostic value in cases of wide angle glaucoma with respect to possible visual field loss.

640 South Kingshighway (10).

I wish to express my gratitude to Dr. L. T. Post, ophthalmologist-in-chief, and Dr. P. T. Shahan, chief of the glaucoma clinic, for making the facilities of the Washington University Eye Clinic available to me, and to Dr. R. G. Scobee for his very valuable advice in the preparation of this paper. The credit for the statistical analysis of the cases must go to Mrs. Hixson of the department of mathematics of Washington University.

THE USE OF BACITRACIN IN OCULAR INFECTIONS*

Part II. Bacitracin Therapy of Experimental and Clinical Ocular Infections

John G. Bellows,† M.D., and Chester J. Farmer,‡ Ph.D.

With the technical assistance of F. W. Kraft and H. J. Reingold.

Chicago, Illinois

In the first part of this report,[1] we have shown that bacitracin may be safely employed on the external surface of the globe in concentrations up to 1,000 units per ml. saline. Bacitracin does not penetrate the normal cornea in appreciable amounts but does penetrate into the aqueous humor when the corneal epithelium is injured by physical, chemical, or infectious agents. Concentrations up to 100 units in 0.05 to 0.1 ml. saline, when injected into the vitreous humor, produced only minimal opacities. No fundus lesions were detectable with the opthhalmoscope. Because of this tolerance of ocular tissues to bacitracin, studies were undertaken to determine its value in experimental and clinical ocular infections.

A. Treatment of experimentally produced corneal infections

The organism used was a pathogenic strain of hemolytic Staphylococcus aureus, was coagulase positive, mannite fermenting, and sensitive to bacitracin. Broth cultures (18 to 24 hours) were used in concentrations varying from the undiluted broth to a concentration of 10^{-6}.

Using a specifically short bevelled 27-mm.-gauge needle attached to a tuberculin syringe, we injected into the corneal stroma in the pupillary area a sufficient amount of the culture to produce a 4-mm. bleb in both eyes. This procedure invariably produced within 24 hours a purulent conjunctivitis with corneal abscess followed by hypopyon and inflammation of the entire anterior segment. If untreated, the infection progressed until it involved most of the cornea, eventually healing with a dense, vascularized scar. In some instances the infection resulted in endophthalmitis or panophthalmitis leading to a granulomatous mass or phthisis bulbi.

For treatment of the corneal infections, bacitracin was used in a concentration of 1,000 units per ml. saline. The experimental procedures are grouped according to the period of time elapsing between inoculation and commencement of therapy, which varied from 30 minutes to 8 hours. In all cases the right eye received treatment, while the left served as a control.

Experimental procedures

In 15 rabbits the undiluted broth culture was employed. In 5 of these animals 2 drops of bacitracin solution (1,000 units per ml. of saline) were applied to the cornea within 30 minutes after inoculation and repeated every half hour for six doses. In no instances was there complete prophylaxis. However, in 4 out of 5 rabbits, the infection in the treated eye was much less severe than in the untreated.

In the next 5 rabbits of this group, treatment was initiated 1½ to 3 hours after inoculation. In these animals the infections in the treated and untreated eyes were equal.

The remaining 5 rabbits of this group received after an interval of one hour, a continuous corneal bath for half an hour in the right and a saline bath in the left eye.

cus aureus were cultured. In 4, the coagulase test was positive and one was negative. In 4, the organisms were found to be sensitive to bacitracin and in one the sensitivity tests were not done. All 5 showed rapid improvement of the acute symptoms with bacitracin therapy. In this group, as in the cases of an acute conjunctivitis, the number of cases is too few upon which to base any final judgment. However, all indications

pointed to the fact that the antibiotic helped in clearing the acute phases of the disease.

Bacitracin therapy in the 18 cases of chronic conjunctivitis treated with bacitracin leaves much to be desired. It appeared ineffective or only of slight value in 12 cases but a rapid improvement followed bacitracin therapy in 6 cases. Therefore, in chronic conjunctivitis, bacitracin was found to be no more effective than sulfonamide, penicillin, or streptomycin used in similar cases.

In the one case of corneal ulcer in which an atypical Pseudomonas aeruginosa was found, rapid recovery followed the institution of bacitracin therapy. Earlier treatment with sulfonamides and penicillin was ineffective.

Discussion

Experimental infections of the cornea and vitreous humor produced by a sensitive strain of hemolytic Staphylococcus aureus can be prevented by bacitracin. Prophylaxis is effective up to 4 hours for the cornea and up to 12 hours for the vitreous infection. In the vitreous, bacitracin will stop the infection even if the antibiotic is injected intravitreally up to 48 hours following the inoculation. This difference in the length of time that prophylaxis is effective in the cornea and in the vitreous humor is explained by the fact that in the latter media the contact between the antibiotic and the infectious agent is constant for a longer period of time.

The safety and effectiveness of bacitracin therapy in experimentally produced infections in the rabbit were sufficiently encouraging to us to use this new antibiotic in clinical ocular infections. Our clinical material consisted entirely of external infections of the eyeball and the adnexa. With the exception of one corneal infection, all cases were of conjunctivitis or blepharoconjunctivitis.

The rapid response to bacitracin in the corneal infection due to an atypical Ps. aeruginosa and in 2 of 3 cases of acute keratoconjunctivitis was significant because the patients had been treated previously unsuccessfully with sulfonamides and penicillin. The effect of bacitracin in the cases of conjunctivitis and blepharoconjunctivitis seemed to depend upon the duration of the infection.

Results in the acute infections or acute exacerbations of the chronic infections, particularly in those in which the organisms were susceptible to bacitracin, were good. In the chronic infections the results were disappointing, leading to the conclusion that bacitracin is no different from the other numerous therapeutic agents, including antibiotics, all of which have been found wanting in chronic conjunctivitis. It is possible that the combination of two or more agents to which the organisms are susceptible may prove to be more satisfactory and should be tried.

Although a suitable case for intraocular injection of bacitracin did not present itself during the time of these investigations, it seems reasonable to assume that in selected clinical cases this procedure should prove valuable. Thus in impending purulent ophthalmia, where the old, conservative measures have invariably failed, a direct intravitreal injection of bacitracin, combined with either penicillin or streptomycin or both, is indicated.

Summary

Bacitracin was found to be well tolerated by the intact eye when applied topically either as a fine powder or in saline solutions containing 1,000 to 5,000 units per ml. On the denuded corneas, solutions containing 1,000 units bacitracin per ml. did not appreciably delay the regeneration of the corneal epithelium. However, a solution containing 5,000 units per ml. caused a definite retardation of the epithelial regeneration with subsequent vascularization and scarring of the cornea.

Bacitracin did not penetrate through the normal cornea but did penetrate injured and inflamed corneas. The penetration following

abrasion of the cornea, vaccinia infection, addition of a surface-active chemical agent (aerosol O. T.), or during ion-transfer, was roughly proportional to the surface area affected. From this we conclude that the penetration depends not so much upon the agent as upon the amount of epithelial damage produced by the agent.

Bacitracin injected into the vitreous in concentrations up to 100 units in 0.1 cc. saline solution resulted in the immediate appearance of vitreous opacities. These frequently disappeared within a period of several weeks. Ophthalmoscopic examination of the oculi fundi failed to reveal any alterations.

Experimentally produced corneal and vitreous infections by the inoculation of a bacitracin-sensitive hemolytic Staphylococcus aureus can be prevented when treated with bacitracin within a definite time interval. Bacitracin will check vitreous-humor infections if injected intravitreally even 48 hours after the inoculation. A single case of corneal infection from which an atypical Ps. aeruginosa was isolated, responded promptly to bacitracin applied locally. Forty-two clinical cases of conjunctivitis and blepharoconjunctivitis were treated with bacitracin. The results on a whole were good in acute infections, in 18 chronic cases improvement followed bacitracin therapy in 6 patients while in 12, the response was less satisfactory or failed completely.

Historical Miniature

Nero is said to have viewed the games through a piece of green beryl. The German name for spectacles, Brillen, arose from the word beryl. Nero may have used the beryl merely as filter for strong sunlight, but it has also been suggested that it may have been a concave monocle for a myopic eye. There is no evidence to substantiate this speculation.

OPERATIVE TREATMENT OF VERTICAL TROPIAS*

BRITTAIN F. PAYNE, M.D.
New York

Surgical relief for the discomfort of vertical tropias has progressed remarkably since Duane and his pupil, White,[1] performed one of the first tenotomies on the inferior oblique muscle. The operation was so successful that the squint was improved, the head tilt was relieved, and the torticollis disappeared. Duane and his protégés continued study and operations on the obliques in spite of the prejudice incited by von Graefe's warning of "hands off the obliques."

The new appreciation of the function and action of the vertically acting muscles resulted in the development of better surgical procedures based on more accurate diagnoses. Just as Duane and White and later Brown[2] have contributed so greatly, Wheeler,[3] Dunnington,[4] Berens,[5] and others have developed new operations and added refinements and innovations to various techniques. Although perfection has not been attained in the field of vertical surgery, the results are improving due to a better understanding of the problems involved.

ROUTINE OF EXAMINATION

Accurate diagosis of the muscle or muscles involved in vertical tropias has such an important bearing on the outcome of surgery that a routine for examination is suggested:

1. History, general and ophthalmic
2. Visual acuity and accommodation determinations, without and with glasses
3. Muscle balance and fusion tests
4. Refraction and correction with glasses
5. Orthoptic treatment
6. Operation and follow up

It is generally agreed that a carefully recorded history of the patient and his antecedents may give valuable information as to the development of strabismus and have considerable influence on the procedure to be followed. The possibility of general disease and nervous manifestations, as well as birth accidents and injuries, should be considered.

In the examination of the patient, a determination of the uncorrected visual acuity should be followed by a record of the vision with glasses. The amount of squint relieved by lenses, if due to accommodation, may alter the extent of the operation.

Estimation of the amount of phoria or tropia in the primary position and in the six cardinal directions of gaze should be performed by means of an opaque disc and square prisms to neutralize the shift of the eyes. A careful observation of the associated parallel movements in the various fields of gaze may give the evidence needed for the diagnosis. Eye dominance is determined because most surgeons prefer to operate on the nondominant eye. The near point of convergence, if present, should be measured. Tests for binocular single vision should include some variation of stereoscopic tests to determine the degree of fusion.

Proper lens corrections, incluring small vertical prisms when needed, should be worn for a reasonable time. If glasses and orthoptic exercises fail to improve the condition, the patient should have the benefit of intelligent surgery. Orthoptic exercises should follow surgery if the degree of fusion warrants it.

Before operating, the surgeon should have a clear picture of the condition as it exists and be sure that surgery will help the condi-

* Presented at the clinical congress of the American College of Surgeons in New York City, September 9, 1947.

Note: The material reviewed for this paper was taken from the six ophthalmic services of the New York Eye and Ear Infirmary with the assistance of Dr. W. F. Johnson, Dr. Carey Legett, Jr., Dr. George O. Emerson, and Dr. Donald S. McCann.

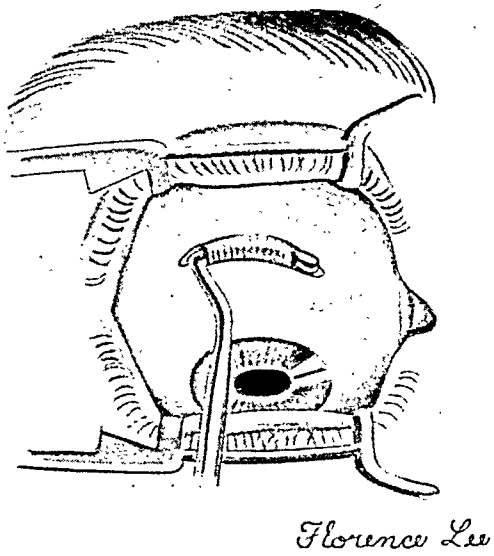

Fig. 1 (Payne). Exposure of the superior rectus muscle for resection.

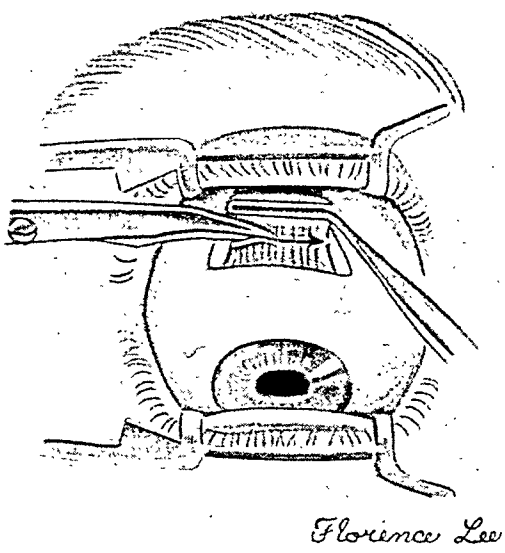

Fig. 2 (Payne). Severance of the superior rectus muscle with fixation clamp applied.

tion and not make it worse. If the patient has no symptoms and is content with his appearance he should be left alone.

Operative objective

The operative objective in the correction of vertical tropias is to give horizontal alignment to the visual axes of the two eyes. This may be done in one of three ways or by a combination of the three.

1. Strengthening the weak or paralyzed muscle by a shortening operation.

2. Weakening the contralateral synergist by a tenotomy or recession.

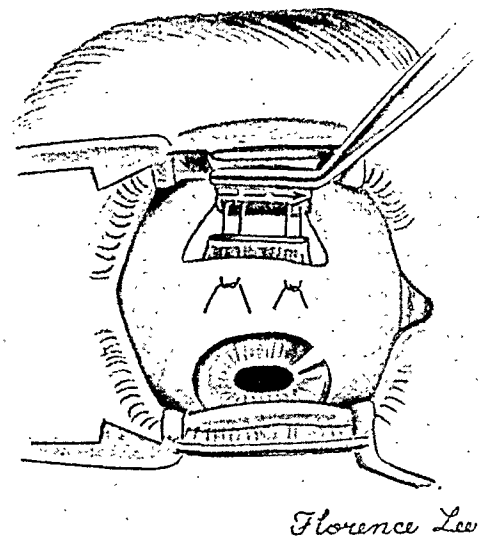

Fig. 3 (Payne). Application of two double-armed sutures posterior to the line of severance.

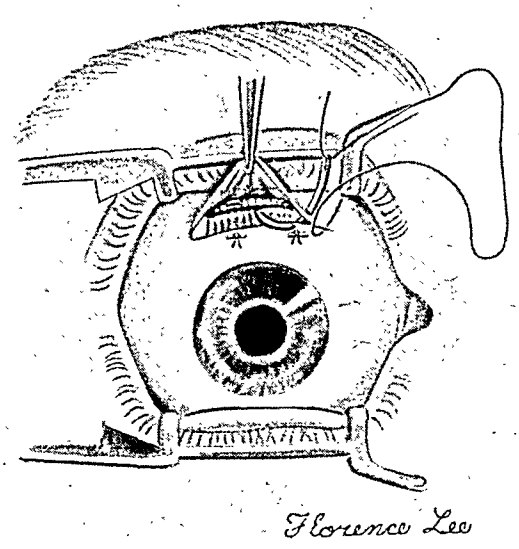

Fig. 4 (Payne). Sutures tied after muscle shortening and beginning of conjunctival closure with continuous stitch.

3. Weakening the antagonist of the same side by recession or tenotomy.

In small degrees of hypertropia, a resection of the semiparetic muscle is preferred to weakening the synergist of the opposite side. A marked upshoot of the synergistic eye caused by an overactive muscle usually needs correction by operation.

Review of cases

A review of 50 of the cases operated on for the correction of vertical tropia on the six ophthalmic services at the New York Eye and Ear Infirmary during the past two years showed that the inferior oblique muscle was selected for surgery in 90 percent of the operations. With the exception of six patients, on whom the inferior oblique alone was operated, either the lateral muscles or the opposite superior rectus were included in the surgery. From these observations it

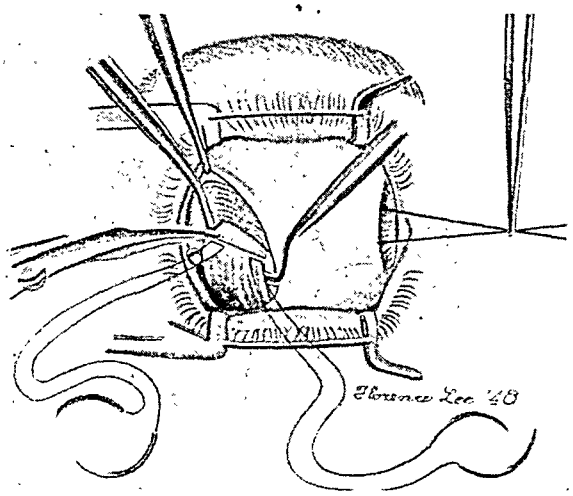

Fig. 5 (Payne). Line of incision and placing of sutures for recession of the right inferior oblique muscle.

would seem that practically all cases of vertical tropia are associated with lateral deviations but that, once the vertical deviation is corrected, either by prisms or operation, the lateral position is diminished and, in small amounts, disappears entirely.

The prevailing operation was recession of the inferior oblique in conjunction with

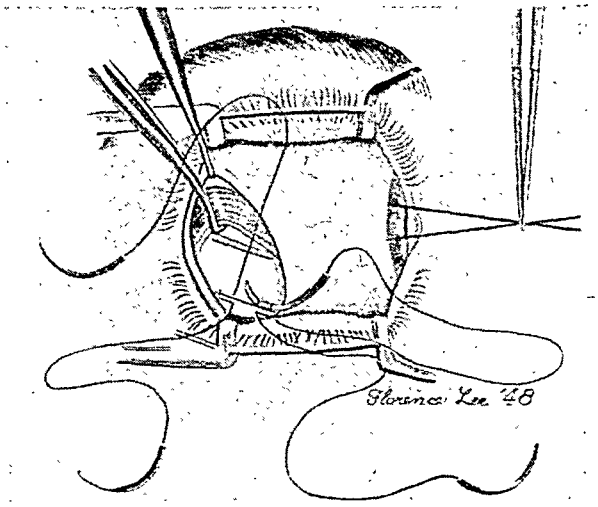

Fig. 6 (Payne). Insertion of sutures into episclera.

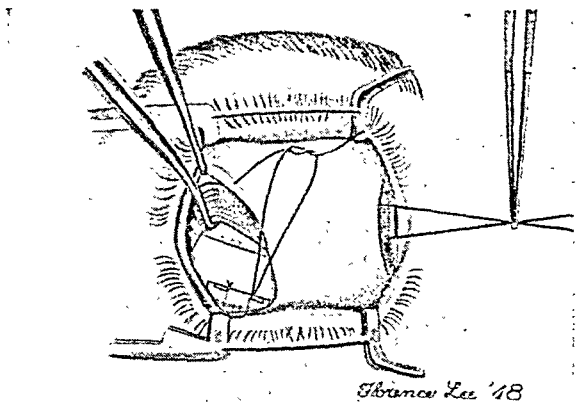

Fig. 7 (Payne). Sutures fixed and tied in episclera.

operations on the horizontally acting muscles. The results were good in 80 percent of the cases but when the diagnosis was uncertain and the operator failed to follow the teachings of Duane, White, Dunnington, and others, he was embarrassed and the patient suffered. There were no operations on the superior oblique in this group.

The following cases illustrated good and bad results in operations for vertical deviations of the eye.

Case reports

Case 1 (C55627). A child, aged 11 years, having 20/40 vision in the right eye with a +0.5D. sph. and 20/30 in the left eye with

the same correction, presented a head tilt to the left shoulder. The near point of convergence was 150 mm. and in the primary position measured an esotropia of 8 prism diopters (p.d.), with a right hypertropia of 25 p.d. both for distance and for near.

On looking up and to the right, there was an exotropia of 3 p.d. On looking to the right, there was an esotropia of 6 p.d. with a right hypertropia of 14 p.d. On looking to the right and down, there was an esotropia of 16 p.d. with a right hypertropia of 14 p.d.

On looking up and to the left, there was a right hypertropia of 40 p.d.; looking to the left, there was a right hypertropia of 50 p.d.; and looking to the left and down, there was an esotropia of 4 p.d. with a right hypertropia of 30 p.d.

The surgery in this case consisted of a 9-mm. recession of the right inferior oblique. This resulted in a change in the near point of convergence from 150 to 55 mm. The right hypertropia for distance and near was reduced from 25 to 5 p.d.

On looking up and to the right, there was a left hypertropia of 3 p.d.; on looking to the right, orthophoria; on looking to the right and down, a right hypertropia of 7 p.d., with an esotropia of 3; on looking to the left and up, there was a right hypertropia of 5 p.d.; on looking to the left, a right hypertropia of 7 p.d.; and on looking to the left and down, a right hypertropia of 12 p.d., with an esotropia of 3 p.d.

In this case there was a change of approximately 2.1 diopters for each millimeter of recession when measured in the primary position and approximately 4 diopters per millimeter of recession when measured in the field of action of the muscle.

Case 2 (C193565). A child, aged 5 years, had 20/30 vision in the right eye, and 20/70 vision in the left eye. The measurements in the primary position at 6 meters were an esotropia of 20 p.d. with a right hypertropia of 2 p.d.; while at 25 cm., there was an esotropia of 25 p.d. and the right hypertropia remained constant at 2. On looking up and to the right, there was a left hypertropia of 10 p.d., plus, and an esotropia of 30. On looking up and to the left, there was a right hypertropia of 12 p.d. (double hypertropia) and an esotropia of 35 p.d.

The following recessions were done: right inferior oblique, 5 mm.; left inferior oblique, 4 mm.; and the left medial rectus, 3 mm.

This resulted in an esotropia of 9 p.d. for distance and 12 p.d. for near with a question of a slight right hypertropia with correction.

On looking up and to the right, there was an esotropia of 8 p.d.; and on looking up and to the left, there was an esotropia of 8 and a right hypertropia of 2 p.d. This resulted in a change of 2½ diopters for each millimeter of recession (the change being measured in the field of action of the muscle).

Case 3 (C21679). A child, 11½ years of age, having 20/30 vision in the right eye with a +3D. sph., and 20/200 n the left eye with a +4D. sph., had a near point of convergence of 40 mm. without correction, and 70, with correction.

The measurements in the primary position at 6 meters were an esotropia of 12 p.d., with correction and 20 without correction; while for near, there was an esotropia of 15 p.d., with correction and 35 without correction.

On looking to the right and up, there was an esotropia of 20 p.d., plus, and a left hypertropia of 2 p.d.

On looking to the right and to the right and down, there was an esotropia of 20 p.d. On looking up and to the left, there was an esotropia of 5 p.d. and a right hypertropia of 2 p.d. (double hypertropia). On looking to the left, there was an esotropia of 18 p.d., and on looking to the left and down, there was an esotropia of 16 p.d.

A diagnosis of convergence excess and bilateral superior rectus paralysis was made.

The following surgery was done: resection of the left lateral rectus, 8 mm.; recession of the left inferior oblique, 5 mm. While this case showed a double hypertropia of 2 p.d. before surgery, it still shows about 2½

diopters for each of the 5 mm. that the left inferior oblique was recessed.

The results were as follows: On looking up and to the right, there was an esotropia of 14 p.d., plus, with a right hypertropia of 10 p.d., on looking to the right, there was an esotropia of 12 p.d., with a right hypertropia of 10; on looking to the right and down, there was an estropia of 10 p.d., plus, with a slight right hypertropia; on looking up and to the left, there was an esotropia of 12 p.d. with a right hypertropia of 14; on looking to the left, there was a question of an exotropia with a right hypertropia of 10 p.d., and on looking to the left and down, there was an esotropia of 12 p.d., with a variable right hypertropia.

Case 4 (C53306). A child, aged 9 years, had 20/30 vision in both eyes and showed, on looking up and to the right, a left hypertropia of 20 p.d. and an esotropia of 40 p.d. On looking to the right, there was a left hypertropia of 8 p.d. and an esotropia of 55. On looking up and to the left, there was a right hypertropia (double hypertropia) of 12 to 15 p.d. and an esotropia of 35 to 40 p.d.

On looking to the left, there was a right hypertropia of 7 to 8 p.d. and an esotropia of 35 to 40 p.d. On looking to the left and down, there was a right hypertropia of 5 p.d. and an esotropia of 50.

The following recessions were done: left inferior oblique, 5 mm.; left medial rectus, 3 mm.; right inferior oblique, 3 mm.; and the right medial rectus 2½ mm. This resulted in an esophoria of 12 p.d. in the primary position.

Apparently, the surgery to the obliques resulted in a change to the hypertropias of about 1½ to 2½ diopters for each millimeter of recession if measured in the lateral positions, and about 4 diopters for each millimeter of recession when measured in the superior cardinal positions.

Case 5 (C72044). This young adult, aged 15 years, had a squint of 9 years' duration. His vision was 20/20 in both eyes and he measured, in the primary position, an esotropia varying between 60 and 70 p.d., with a left hypertropia of 10 p.d.

Looking up and to the right, there was a left hypertropia of 14 p.d., and in the other cardinal positions of gaze there was a left hypertropia of 8 to 10 p.d.

After a resection of 10 mm. on the right lateral rectus, 9 mm. on the left lateral rectus, and a recession of 3 to 4 mm. on the left inferior oblique, there resulted in the primary position an esotropia of 12 p.d. and no hypertropia. In this case the surgery to the left inferior oblique resulted in a change of about 3 diopters for each millimeter of recession.

Case 6 (B91919). This last case is included through the courtesty of Dr. W. F. Johnson and preoperatively presented a head tilt to the left, and a near point of convergence of 130 mm. In the primary position, without correction, there was a right hypertropia of 35 p.d., with an exotropia of 15 p.d. for distance; while for near, there was a right hypertropia of 18 p.d. and an exotropia of 18. The field of binocular single vision extended from the right to eyes front. On looking up and to the left, there was a right hypertropia of 30 p.d.

In this case, a 9-mm. recession of the right inferior oblique was performed. Following surgery, the field of binocular single vision was enlarged to the left; the head was held straight, the near point of convergence was reduced from 130 to 60 mm.

In the primary position, without correction, for distance and near, there was an exophoria of 5 to 8 p.d., with a slight right hypertropia. On looking up and to the left, there was a right hypertropia of 5 p.d. So in this case, for each millimeter the right inferior oblique was recessed, there was a change of 2 to 2½ diopters.

Discussion

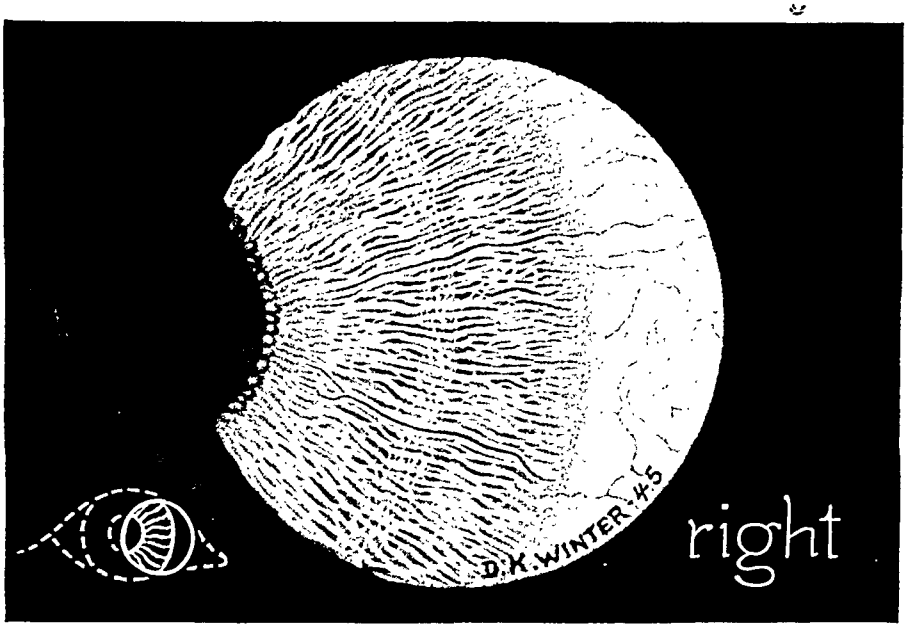
From the above cases it will be seen that, with each millimeter of recession of the inferior oblique, approximately 2½ prism diopters of correction was attained. These

operations were performed by both residents and surgeons and included the lateral muscles. The evidence is not uniform and it is doubtful if the figure is of any practical value. It is interesting to note, however, that the same findings hold true in the unsuccessful case mentioned above.

Aside from Johnson's[6] simplified approach to the inferior oblique, which is similar to the linear incision parallel to the lower border of the lateral rectus used by Berens,[7] no new procedure has been developed at the New York Eye and Ear Infirmary. There is a tendency of some surgeons to use 4-0 plain catgut sutures rather than nylon or silk for the scleral reattachment of the muscle. Absorbable sutures hold the muscle in place for a sufficient length of time and there is little reaction to them.

A word of warning with reference to the important structures in the neighborhood of the scleral attachment of the oblique muscles is directed to the neophyte. There is danger of injury to the long ciliary nerve and parts of the muscular attachments are very close to the macular region. The vortex vein is exposed frequently and subject to trauma and the surgeon should remember that anomalous attachments between the oblique muscles and the lateral rectus may be found.

It is well to repeat Krewson's[8] conclusions that, if a choice is permitted, weakening of a depressor muscle is undesirable; strengthening of a depressor or weakening of an elevator muscle is preferable, for there is greater need for binocular vision in the lower than in the upper fields.



Conclusions

1. Carefully planned operations for the relief of vertical tropias are successful if the diagnosis is correct.
2. A clear understanding of the muscle or muscles involved is essential.
3. The type and extent of the operation will be determined by the points brought out in the complete examination.
4. Injury to neighboring structures should be avoided.

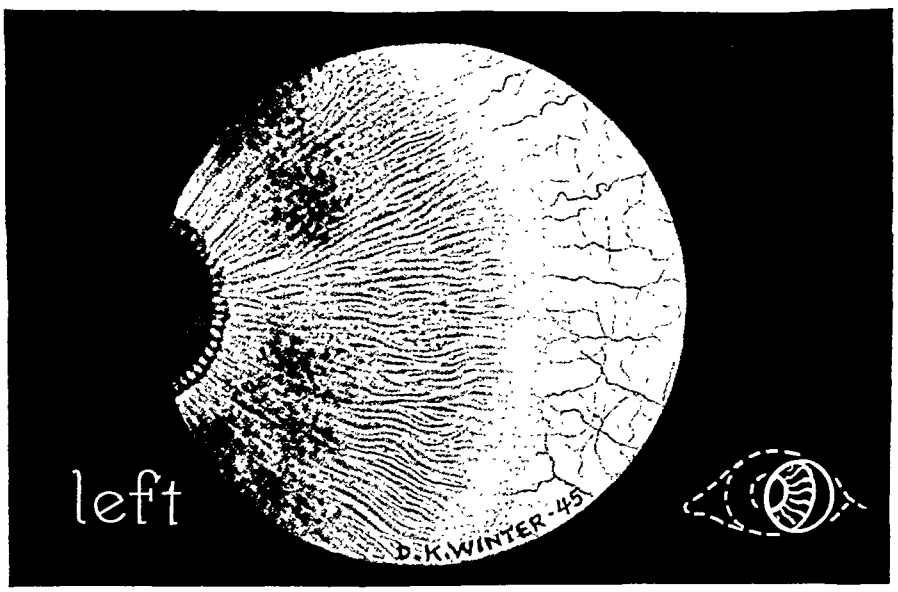

FIG. 1 (RICHARDSON). CASE 1. DRAWINGS OF QUADRANTS OF IRIS. RIGHT, THE UNAFFECTED EYE. LEFT, THE AFFECTED EYE.

DIFFUSE MALIGNANT MELANOMA OF THE IRIS*

Report of two cases

Shaler Richardson, M.D.
Jacksonville, Florida

A survey of the literature offers convincing evidence of the rarity of primary malignant melanoma of the iris. The number of recorded cases is estimated by Duke-Elder[1] at 150 and by Doherty[2] at about 175. It is generally stated that of malignant melanomas in the uveal tract, 85 percent occur in the choroid, 9 percent in the ciliary body, and 6 percent in the iris. McKee[3] observed that this ratio is somewhat proportional to the amount of uveal pigment present.

Usually circumscribed, this lesion of the iris may be diffuse, and it may also be pigmented or unpigmented. Although the descriptive literature is often not explicit enough to make differentiation between the circumscribed and the diffuse types clear, the diffuse tumor appears to be extremely rare. Recently, Wilder[4a] stated that there are 7 instances of diffuse malignant melanoma of the iris in the files of the Army Institute of Pathology. In presenting 1 case in 1923, Li[5] was able to collect only 5 cases in the literature. Doherty[2] in 1939 included in his complete bibliography (1919-1937) but 5 additional cases, designated as ring sarcoma of the iris. Among the 263 cases of uveal sarcoma in Martin-Jones's recent comprehensive study,[6] there was 1 case of ring sarcoma. Two cases that came under my care within a period of 13 months are reported here.

Nomenclature

Malignant melanoma of the iris is variously referred to in the literature as sarcoma, melanosarcoma, and ring sarcoma. Malignant melanoma is, however, to be preferred. In the view of some authors, melanoma carries with it the connotation of malignancy, and nevus is applied to the nonmalignant pigmented tumor. Nevertheless, in opthalmology there is need for the more exact definition of benign or malignant melanoma, for in the eye are present mesodermal melanoblasts, from which arise both benign and malignant tumors.[7] When not circumscribed, the malignant melanoma of the iris is appropriately described as diffuse or infiltrating. First differentiated by Fuchs,[8] this type came to be described as flat sarcoma, and, in 1898, Ewetzky[9] suggested the term ring sarcoma, which seems to have the preference in the literature.

Age and sex incidence

Most authorities are agreed that malignant melanoma of the uveal tract is more prone to develop in persons in the sixth decade. It has been noted, however, that in the iris this tumor occurs on the average some 10 years earlier than those in the ciliary body and choroid, at approximately the age of 40 years instead of 50 years. This conclusion is borne out in my cases. Wilder[4b] mentioned a series of 137 malignant melanomas of the iris in which 51, or 37 percent, were from patients under 40 years of age, confirming Duke-Elder's statement that the average age of occurrence for tumors of the iris is lower than for the remainder of the uveal tract.[1]

Martin-Jones[6] concluded that this neoplasm of the iris occurs with greater frequency in women. Three of the 4 cases in his recent series, including the 1 case of ring sarcoma, were in women, and he cited Pflüger's 23 cases with 15 in women and Treacher Collins' 18 cases with 10 in women. Five cases of ring sarcoma cited by Li[5] were in women, although his 1 case was not, nor was Bruner's case.[10] In 1 of my 2 cases the patient was a woman.

* Presented at the 83rd annual meeting of the American Ophthalmological Society, Hot Springs, Virginia, June, 1947.

Etiology

The method of origin of the malignant melanoma remains a matter of controversy. Opinions vary as to whether it arises from endothelium, epithelium, or chromatophores. In contradistinction to the epiblastic theory of Verhoeff,[11] there is the more recent neuroectodermal theory advanced by Masson[12] and supported by the later researches of Theobald.[13]

The role of injury in the etiology of this tumor is problematical, as is that of prolonged inflammation. It is, however, well known that benign melanomas of the iris undergo malignant changes and should rightly be regarded with suspicion. Martin-Jones[6] concluded that abnormal ocular pigmentation is an etiologic factor in some cases of sarcoma of the uveal tract, the evidence being more in favor of abnormal masses of pigmentation in the iris becoming malignant than those of the choroid.

Reese[7] concluded that a melanoma of the uvea may be malignant at one site and benign at one or several other sites, thus representing multiple origins of the tumor. Noting that the iris is a common site for the benign feature, he regarded this lesion of the iris as a diagnostic aid when observed clinically. He commented that the ring nature of a melanoma may be accounted for in part by multiple diffuse origins as well as implantation growths which logically occur around the filtration angle, where disseminated tumor cells in the anterior chamber would tend to gather. Too, he was of the opinion that an important difference between a localized malignant melanoma of the uvea with benign melanomas elsewhere and a diffuse and ring type of melanoma lies in a malignant effect of the cancerigenic agent at one site and a benign effect elsewhere in the one case, and a diffuse, multiple, malignant effect in the other cases.

Pathology

The cell types on which the classification of Callender[14] is based include spindle cell with subtypes A and B, fascicular, epithelioid, mixed, and necrotic. From their study of 500 cases of malignant melanoma of the choroid and ciliary body, Callender, Wilder, and Ash[15] concluded that the pure spindle cell types, particularly subtype A, are of a relatively low degree of malignancy, that an increased degree of malignancy is associated with the presence of epithelioid cells, and that a low degree of malignancy is usually associated with a heavy fiber content. Wilder[4b] explained the observation that melanomas of the iris behave less malignantly than do those of the choroid on the ground that they are readily visible and consequently recognized earlier.

Whether the tumor starts at the root of the iris or in the region of the ligamentum pectinatum, these structures as a rule become rapidly involved. An increase in size denotes the extension in a definite pigmented nevus. If, however, the growth originates in the deeper layers of the iris near its root, it may spread beneath the stroma, causing discolorations varying from light yellow to dark brown. This type of growth tends to metastasize into the fibers of the ligamentum pectinatum and the canal of Schlemm, with resulting increased tension. Metastasis around the angle of the anterior chamber produces the diffuse or ring type of tumor.[2]

In its evolution, the diffuse tumor is distinguished from the circumscribed variety by its slow growth with long preservation of vision and lack of objective signs, its diffuse infiltration of the uveal tract, and the extent of its metastatic spread. Duke-Elder[1] estimated the length of the history from 7 months to 10 years and regarded it as the most conspicuous feature. In this connection it is of interest that in Bruner's case,[10] the patient "had always noticed a little colored spot on the inner half of the iris." In Li's case,[5] there was a history of trauma 2 years previously. Of the cases collected by Li,[5] in Solomon's case,[16] the patient had observed for 20 years a speck on the iris gradually increasing in size; in Hanke's case,[17] the

growth evidently antedated the failing vision of 9 months' duration by a considerable period; in Alt's case,[18] the patient had observed a spot on the iris for several years; in Levan's case,[19] a pigmented nevus was observed for several years with increase in size and several pigmented spots not noted previously appearing 1 year before removal of the eye; and in Pindikowski's case,[20] the patient had noticed the tumor for some time. In my cases, 1 patient thought that the affected eye had been discolored for several months, and the other patient had been aware of a dark brown spot on the iris of the involved left eye for many years with gradual change in color of the iris to dark brown over an indefinite period of years, the iris of the right eye being blue.

Diagnosis

It may be impossible at first to distinguish between benign and malignant melanomas unless microscopic examination is made possible by iridectomy. The benign lesion characteristically attains a certain size and remains so; it does not project much above the plane of the iris. Too, vascularization is uncommon in the innocent tumor. Beginning malignancy manifests itself clinically by an increase in size, varying discolorations in the same growth, an increased blood supply, an elliptical pupil, and development of abnormal tension.[2]

Martin-Jones[6] observed that malignant melanoma of the iris may give rise in some cases to no subjective symptoms, being discovered only on routine examination; in other cases, the patient may seek advice because of a small brown or blackish spot on the iris, present as long as he could remember or since birth, and believed to be increasing in size. Extension of the growth over the pupillary margin may interfere with vision, as may intraocular pressure if the tumor grows sufficiently. Analysis of the pathologic reports in my cases would seem to indicate that the glaucoma was secondary to the infiltration of pigment and tumor cells into the filtration angle.

The position on the iris is a consideration of some importance in diagnosis. In the order of frequency, the lower half, the upper half, the inner segments, and the outer segments are affected.

In differential diagnosis, inflammatory granulomas, especially tubercle and syphilis, are to be considered, as are secondary tumors and cysts. The flat diffuse lesion is sometimes mistaken for iridocyclitis. When the secondary glaucoma manifests itself, it is difficult to be sure that this condition is not primary.

Prognosis

Despite the relatively slower progress of malignant melanoma in the iris, the prognosis is uncertain at best. There appears to be no time limit of safety. Even enucleation at an early stage does not preclude metastases, and, after extraocular extension, fatalities rapidly increase. Infiltrating growths are more dangerous than the discrete variety.

Considering this tumor in the uveal tract as a whole, Martin-Jones[6] concluded that the case is quickly and invariably fatal if melanogen is present in the urine. It was not present in either of my cases. This author further observed that 27 percent of patients die within 3 years after operation, 36 percent within 5 years, and 56 percent within 10 years; that the mixed-cell type of growth is the most malignant; that the presence of malignant cells in the emissaria of the globe is not necessarily of bad prognostic import (in 58 percent of such cases survival reached 5 years); that the prognosis in cases of extraocular extension is comparatively bad (70 percent of patients died from the disease within 5 years); and that in younger patients the prospect of survival from the disease is better than in those more advanced in years.

The spindle-cell type of lesion with a delicate nuclear structure gives the best and the round-cell epithelioid and the mixed-cell

types the poorest prognosis. Also, the less dense the intercellular reticulum the graver the prognosis, according to Duke-Elder.[1] Their work on the prognostic significance of reticulin, or argyrophil, fibers led Callendar and Wilder[21, 22] to conclude that there is an apparent connection between the reticulin content of the growth and the prognosis. Callender, Wilder, and Ash[15] mentioned an apparent increased lethality with increased pigment content, but withheld a definite conclusion.

Treatment

Once the diagnosis of diffuse malignant melanoma of the iris is established, enucleation without delay is the treatment of choice. This extreme measure is the only procedure that offers relative safety. It would appear that exenteration does not increase the chance of survival in cases of extraocular extension.

There is apparently no evidence to justify radiation as a primary method of treatment. Some authors think it may have value as a postoperative measure.

Case reports

Case 1

History. Dr. A. J. O., a dentist aged 40 years, was examined on June 9, 1945. He complained of photophobia of 6 months' duration and a slight blurring of vision of the left eye of 7 days' duration. He stated that he had had no previous ocular trouble other than an astigmatism, for which glasses were worn, but he thought the left eye had been discolored for several months.

Examination. The vision in the right eye was 20/15, and in the left eye it was 20/20. The right eye was normal in all respects; the iris was light brown in color and without freckles (fig. 1R).

In the left eye, mild ciliary injection, sensitivity to light, and mild edema of the corneal epithelium were present. The aqueous contained a few cellular elements and, with biomicroscopy, the aqueous beam was hazy. The pupil was slightly dilated ovally, but reacted to light in its upper half. The iris was densely pigmented, its color being dark brown, but in its upper segment a few islands showed no pigmentary changes (fig. 1L). Below, there were 3 pigmented nodules rising slightly above the surface of the iris. Biomicroscopy showed dense pigmentation of the iris extending into the filtration angle. On the posterior surface of the cornea there were deposits of pigment. No new blood vessels were noted.

Intraocular pressure was: R.E., 19 mm. Hg (Schiøtz); L.E., 50 mm.

A 2½-percent solution of neosynephrine was instilled twice. The pupil dilated slightly above, but in the lower segment of the iris where pigmentation was heaviest, there was no dilation. The use of neosynephrine for dilation of the pupil was deemed necessary in order to examine the posterior chamber. The ocular fundus was normal; there was no cupping of the optic disc. The fields of vision were within normal limits.

Consultation. The patient was told that in my opinion a malignant melanoma of the iris was present and that enucleation was imperative. Consultation was advised, and he was referred to Dr. A. B. Reese, who, in confirming the diagnosis, wrote me on July 27 as follows:

"I agree most assuredly with you that Dr. O. has a malignant melanoma of the iris of the left eye. I do not feel there is any doubt at all about this. This melanoma is a flat, diffuse type which gives early glaucoma and is sometimes mistaken, particularly in the early stages, for iridocyclitis. I have seen 2 such instances, in which the eyes were operated on for secondary glaucoma. With the gonioscope, I noted the angle over the lower 180 degrees occluded by the tumor tissue."

The patient then returned to me. On August 2nd, the eye was enucleated, and a vitallium sphere was implanted in Tenon's capsule.

Pathologic report. The pathologic report made by Dr. J. A. C. Wadsworth of the College of Physicians and Surgeons, Columbia University, follows.

Microscopic. The sections are from an adult globe in which there is a heavily pigmented tumor of the iris and ciliary body which in its growth has involved the filtration angle (fig. 2).

Near the base of the iris below is a loosely packed, heavily pigmented tumor mass which has spread diffusely throughout the iris and into the ciliary body. The tumor cells with their heavy pigment content can be seen clogging the meshwork of the angle and Schlemm's canal.

On the posterior surface of the cornea near the angle below, a thin layer of tumor cells can be seen extending axialward. Many of these cells contain pigment. Also, scattered irregularly over the entire posterior surface of the cornea are numerous individual implants of tumor cells. Below, the iris is almost completely infiltrated with tumor cells, and those in the stroma of the iris contain no pigment or are very scanty in pigment. The contraction of this infiltrative growth has created a well-marked ectropion uveae.

The tumor extends back from the base of the iris to the base of the ciliary body. In the region of the main mass of the tumor, pigmented cells can be seen coursing along the perivascular spaces into the sclera, but no tumor can be seen outside the confines of the globe in the sections examined.

The majority of the tumor cells are large, oval, and epithelioid in type, and filled with round pig-

ment granules (fig. 3). Occasionally one sees the branching typical of the chromatoblastic type of cell. The numerous implants along the cornea and throughout the iris and into the meshwork of the angle indicate the extreme friability of the tumor, and a marked tendency of the tumor cells to desquamate and disseminate which is typical of the chromatogenic type.

Sections stained with the Wilder method show a moderate amount of reticulum. Sufficient reticulum is present in the tumor to be placed in 2-c according to the Wilder classifications.

In the ciliary body opposite the site of the tumor there are areas of proliferation of the pigment epithelium with an associated proliferation of nonpigmented epithelium.

The retina shows peripheral cystic degeneration, and scattered throughout the retina are numerous small cystic areas. These areas are seen in the ganglion cell layer and external plexiform layer. There is also wrinkling of the internal limiting membrane of the retina.

The choroid is normal except for occasional drusen of the lamina vitrea.

There is moderate cupping of the optic nerve.

Diagnoses. Tumor of iris: melanoma—malignant (disseminating type). Tumor of ciliary body: melanoma—malignant (disseminating type). Glaucoma: secondary to tumor. Ciliary body: hyperplasia of ciliary epithelium.

Course. Recovery was uneventful. When the patient was examined on May 1, 1947, 22 months after enucleation of the eye, there was no evidence of recurrence or metastasis.

CASE 2

History. Mrs. W. L. P., a housewife aged 39 years, was referred to me in consultation by Dr. R. L. McDaniel on May 5, 1944, with the tentative diagnosis of malignant melanoma of the iris of the left eye. She stated that this eye had been red and had ached for 3 days, but there was no history of previous trouble with the eyes. Over an indefinite period of years she had observed the iris of the left eye become dark brown and she had also noticed a dark brown spot on it for many years. The iris of the right eye was blue, with no deposits of pigment.

Examination. On examination, the conjunctiva of the left eye was mildly hyperemic, and there was congestion of the ciliary vessels. Intraocular pressure was: R.E., 19 mm. Hg (Schiøtz); L.E., 40 mm.

The iris of the left eye was uniformly colored a chocolate brown and had the appearance of having had brown pigment spread on its surface. Its normal markings were effaced by the deposits of pigment, and it seemed thicker than usual. The pupil did not react to light; it was slightly dilated and, in the pupillary circle, ectropion uveae was observed. Biomicroscopy showed a slight edema of the corneal epithelium. The aqueous beam was hazy, and within the aqueous fine pigment granules were noted. The filtration angle was covered with pigment over its entire circumference. Fine deposits of pigment were observed on the posterior surface of the cornea and on the anterior capsule of the lens.

A 2½-percent solution of neosynephrine was instilled, but the pupil did not dilate. The ocular fundus was normal except for a pathologic cupping of the nerve head.

The right eye was normal in all respects. The vision in this eye was 20/15, and in the left eye it was 20/20. The field of vision of the left eye was contracted concentrically to 20 degrees for form.

Diagnosis. It was difficult to identify this condition positively as a melanoma of the iris. Uveitis could not be ruled out clinically, nor could glaucoma. A diagnostic iridectomy was therefore performed on May 5th. The pathologic diagnosis was malignant melanoma, and the eye was immediately enucleated (fig. 4).

Pathologic report. The following pathologic report of the enucleated eye was made by Col. J. E. Ash, director of the Army Medical Museum.

Gross. The specimen consists of a firm, rather large eye measuring 26 by 24 by 25.5 mm. There is a scar at the limbus over a coloboma of the iris. The pupil is widely dilated, revealing only a narrow margin of the iris. The eye is opened in the vertical plane. There is a fold at the macula. The optic disc is cupped.

Microscopic. The iris is absent beneath a partially closed scar of a perforating wound of the cornea near the limbus (fig. 5). On the opposite side generally round or polygonal cells, although occasional spindle forms are seen, infiltrate the iris and vascular layer of the ciliary body (fig. 6). On both sides they line the filtration angle, clog the spaces of Fontana, and appear around the canal of Schlemm (fig. 7).

The tumor cells are, on the whole, rather heavily pigmented, but the round, very deeply pigmented cells which cling to the filtration angle and the anterior surface of the iris are probably chromatophores. In the iris the tumor cells are concentrated anteriorly although, in some areas, they penetrate to the dilator muscle. A Wilder reticulum stain demonstrates an argyrophil fiber content of about 50 percent. Subuveal hemorrhage detaches the ciliary body and all but the posterior choroid. The lamina cribrosa appears somewhat depressed.

Diagnosis. Diffuse malignant melanoma of the iris, mixed-cell type, with invasion of the ciliary body; secondary glaucoma; iridectomy; subchoroidal hemorrhage.

The patient was recently examined 3 years after removal of the eye. There was no indication of recurrence or metastasis.

DISCUSSION

In both cases the filtration angle was blocked with pigment and tumor cells, there

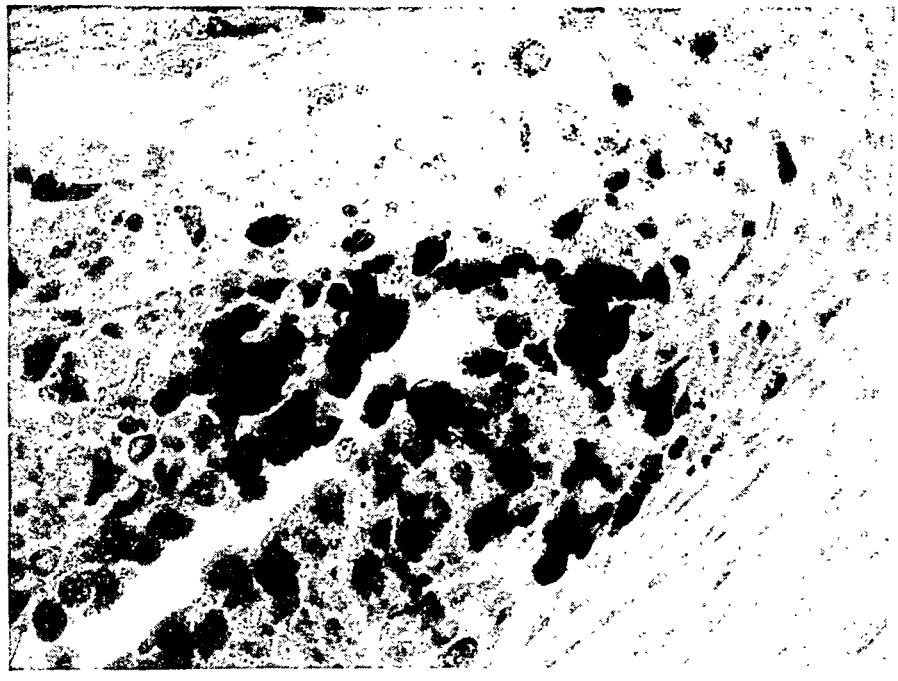

Fig. 7 (Richardson). *Case 2.* Photomicrograph showing section of the iris at the filtration angle.

was secondary glaucoma, deposits of pigment were present on the posterior surface of the cornea, and the anterior chamber was normal in depth. Also, vision was within normal limits in both cases. In Case 1 the pupil dilated only partially and in Case 2 not at all.

Reticulum stain by the Wilder method demonstrated reticulum content of more than 50 percent in Case 1 and about 50 percent in

Case 2. The lesion was of the epithelioid type in Case 1 and of the mixed-cell type in Case 2.

It is noteworthy that in Case 2 a pigmented spot or freckle on the iris of the affected eye was observed by the patient for some years prior to the development of the tumor.

SUMMARY

Diffuse malignant melanoma of the iris occurs rarely. The salient features of this unusual lesion are presented.

Two cases of malignant melanoma of the diffuse type primary in the iris are reported.

111 West Adams Street.

THE ELLIOT TREPHINING OPERATION FOR GLAUCOMA*

A PROCEDURE TO MAKE THIS OPERATION LESS DIFFICULT AND MORE EFFECTIVE

RAYMOND EMORY MEEK, M.D.
New York

Medical treatment of glaucoma has its limitations and in many cases it fails, at which time surgery becomes necessary. Some eye surgeons even go as far as to advise operation in all cases of early glaucoma.

INTRODUCTION

There are various operations used to reduce increased intraocular pressure, among which are the paracentesis and posterior sclerotomy operations. These procedures afford temporary reductions in tension. Paracentesis of the cornea may be done to lower the tension in the more severe degrees of glaucoma until such time as a more permanent procedure may be safely carried out.

It is dangerous to lower the pressure suddenly in an eye with a tension above 40 mm. Hg (Schiøtz). Therefore, it is recommended that in the morning of a contemplated operation—as for instance a trephining operation—a paracentesis be performed to lower the tension. This is done obliquely through the cornea so that on withdrawal of the keratome the wound immediately seals itself. Pressure on the posterior lip of the wound to permit the aqueous to escape a little at a time gradually lowers the tension. A dressing is applied and by midafternoon the tension will again be up to about 30 mm. Hg or more. The operation can then be carried out with less chance of complications, such as a hemorrhage or a sudden exodus of aqueous carrying a ciliary process into the opening. In a case with a shallow anterior chamber no paracentesis is attempted. A small posterior sclerotomy may be made, or preferably an iridectomia ab externo.

ELLIOT'S OPERATION

The Elliot trephining operation, of late, has seemed to fall more and more into disuse. It has been criticized on the ground of being followed too frequently by secondary infection. In this respect Fuchs[1] remarks, "Statements with regard to secondary infection vary greatly. On the whole it does not seem to occur often if the operation is properly performed."

The incidence of late infections has been variously reported[2] as from none to 13.6 percent. Wilmer[3] came to prefer trephination to all other procedures in glaucoma, and reported 88-percent successes and only one late infection in a series of 107 cases. Of these cases, most were observed for 5 to 15 years. If a tension of less than 18 mm. Hg (Schiøtz) was maintained without the use of miotics and the field and visual acuity remained as good or better than before operation, he considered the operation a success.

If such results can be obtained, the operation deserves more popularity than it enjoys at present. Difficulties in the technical aspects of the procedure seem to explain much of its decline in popularity. Surgeons employing this method complain of buttonholing the conjunctiva, of getting a shelf due to failure to get a clean-cut opening, of difficulty in grasping the iris due to its failure to prolapse, of losing the plug in the anterior chamber, of failure to maintain a reduced tension because of dense scar formation, and of the occurrence of secondary cataract.

MODIFICATIONS IN OPERATION

The object of this paper is to present a simple technique in performing the Elliot corneoscleral trephining operation and to restore this operation to its proper place as a means of relieving tension in glaucoma.

Benedict's conjunctival flap

Benedict's[4] able paper brought out a proper approach to the limbus. The conjunctiva and Tenon's capsule are cut through, baring the sclera 8 mm. above the limbus. These tissues are undermined right down to the insertion of Tenon's capsule, 3 mm. from the limbus. Here Tenon's capsule is separated from the sclera and the undermining is continued to the attachment of the conjunctiva at the corneoscleral margin. This approach minimizes the trauma to the subconjunctival tissues through which drainage must occur, and makes the wall of the filtering bleb thicker.

Incisions

Attempting to split the cornea is a step where most operators run into difficulty. They make an effort to cut the outer scleral fibers of the corneoscleral margin obliquely with pointed scissors or a sharp dissector and then attempt to split the outer layer of the cornea with a blunt dissector.

The outer layers are not severed and the attempt made to force a spatula into the corneal stroma therefore fails. One small slip and the conjunctiva is buttonholed. The surgeon must then stop and suture this conjunctival tear, or he may enlarge the tear to do a peritomy. When a peritomy has been done the conjunctiva is retracted toward the fornix and away from the limbus exposing the corneoscleral margin.

The trephine is then applied. The cornea about the trephine opening must then be scarified and the conjunctival flap pulled down and sutured to it so as completely to cover the opening. The conjunctiva readily adheres to the scarified cornea around the trephine wound. When simple suturing of the buttonhole is done, the trephine opening may be done to one side of it.

Trephine openings

Trephine openings have been purposely made in the sclera above the limbus. This I do not advocate for two reasons: (1) because this opening is a sclerectomy which may fill with fibrous tissue in about two weeks, and (2) because it places the wound in the apex of the angle of the anterior chamber where the ciliary processes can readily prolapse into it.

Fig. 1' (Meek). Ciliary process from the iris.

Fig. 2 (Meek). Ciliary process from the iris.

Fig. 3 (Meek). Ciliary process from the iris.

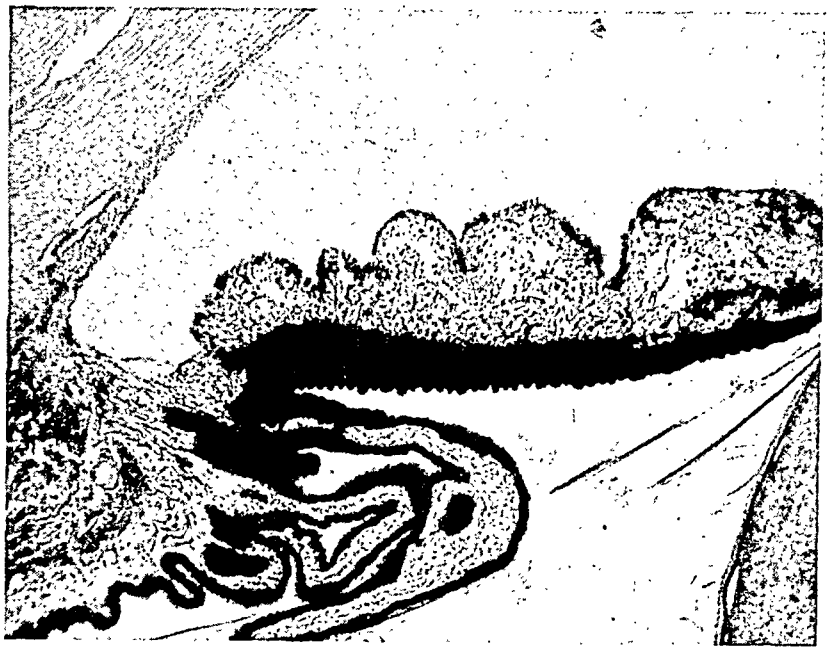

Fig. 4 (Meek). Ciliary process from the posterior surface of the iris root.

Reese[5] has found ciliary processes extending as far forward as the equator of the lens and in some instances has even found them arising from the posterior surface of the iris. This can account for failures with the trephine opening because a ciliary process may block the trephine opening.[6] Placing the trephine opening to the extent of 0.75 mm. in the cornea will reduce the likelihood of such blockage.

In a study of histologic sections of human eyeballs in the Eno Laboratory of the New York Eye and Ear Infirmary, my findings substantiate those of Reese (figs. 1-6).

Technique of new procedure

The method of approach here advocated is to make the conjunctival-Tenon's flap by Benedict's method until the corneoscleral junction is reached. The flap is drawn down over the cornea with a toothpick point covered with wet cotton laying bare the corneoscleral margin.

A Wheeler or Lundsgaard knife is now held lightly between the fingers and thumb. With the blade perpendicular to the surface, the corneoscleral junction is gently sliced until the tissues are half cut through. By so cutting the tissues, the splitting of the cornea is no problem at all. An ordinary iris repositor easily separates the fibers of the cornea. In fact, with very little pressure, the iris repositor may be pushed down between the lamellae as far as one third of the vertical diameter of the cornea.

A 1.5-mm. trephine is used. With about 1 mm. of the cornea now denuded of its outer

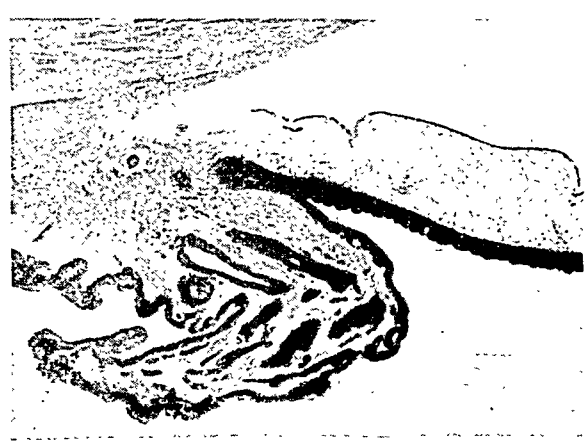

Fig. 5 (Meek). Ciliary process from the junction of the iris and the ciliary body.

Fig. 6 (Meek). Ciliary process from the posterior surface of the iris.

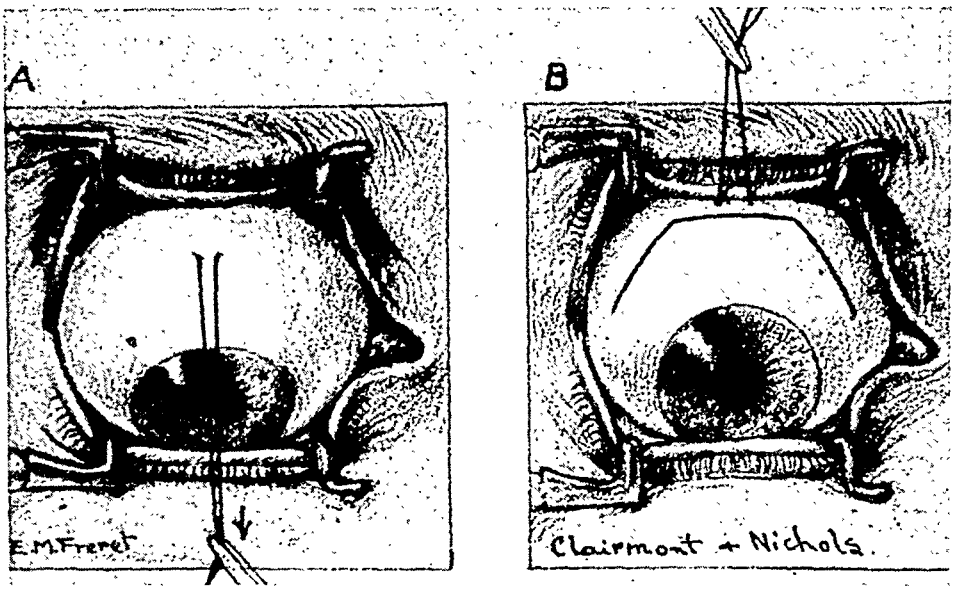

Fig. 7 (Meek). (A) A stay suture is placed in the tendon of the superior rectus muscle. (B) An incision is made with scissors through the conjunctiva and Tenon's capsule down to the sclera.

half, the trephine may be applied above and slid down over the split cornea using the lower raised anterior section of the cornea with its attached conjunctiva as a shelf to hold the trephine in position. In Negroes or highly pigmented persons the cornea is split for a distance of 1.5 mm. from its limbus and, a 2-mm. trephine is used (figs. 7-13).

Gentle rotation of the trephine is now started. The trephine is removed from time to time to be sure that it has not penetrated into the anterior chamber.

Elliot[7] recommended tilting the trephine forward to get a hinge on the corneoscleral disc on its scleral side. Others suggested tilting the trephine back to get an anterior hinge, or to the right or the left side. Such hinges are undesirable because often they form so large a shelf or obstruction that the iris can not prolapse.

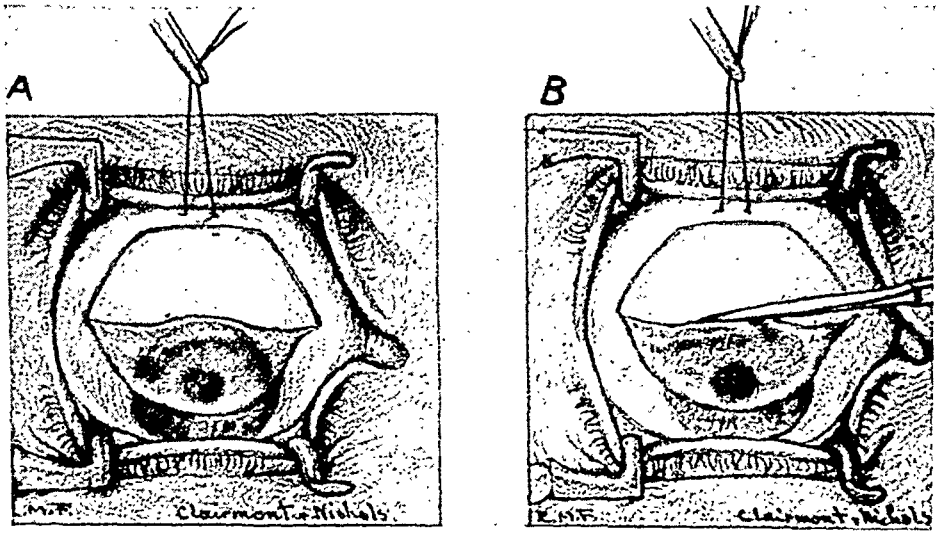

Fig. 8 (Meek). (A) The conjunctiva and Tenon's capsule are undermined down to the limbus. (B) The blade of a Wheeler knife is held perpendicular to the corneoscleral margin.

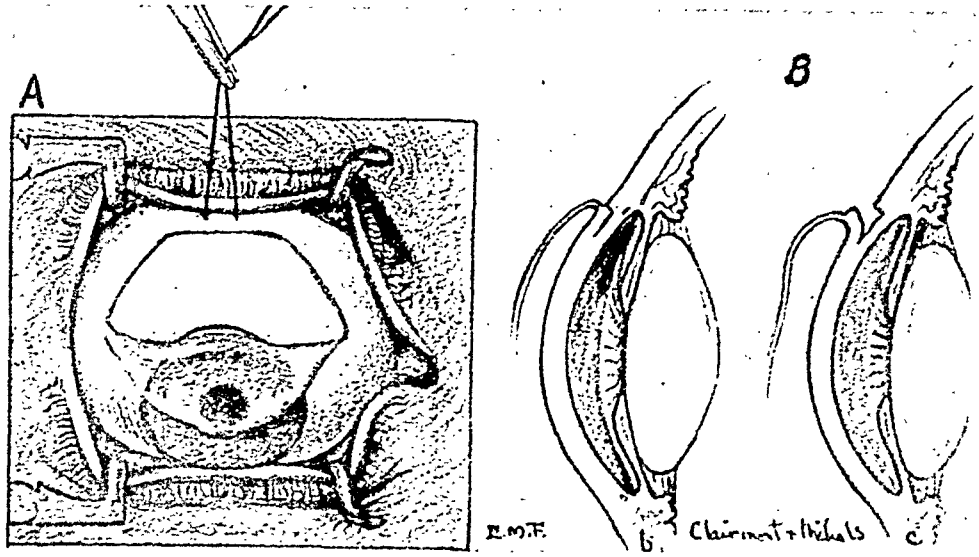

Fig. 9 (Meek). (A) The corneoscleral margin is sliced half-way through. (B) Diagram to show where the tissues are separated by a spatula.

It is best to hold the trephine perpendicular to the corneoscleral margin. With care, a distinct sensation is felt when the trephine penetrates into the anterior chamber. The trephine should then be removed immediately. A trephine with a collar may be used advantageously to avoid penetrating too deeply.

Usually, when the trephine is withdrawn, the iris prolapses at once from the opening, pushing the plug ahead of it. The plug may be removed first if free, and the iris then picked up and incised. If the plug is still adherent, plug and iris are cut together.

In any case, the iris, after being grasped with forceps, must be pushed down toward the center of the cornea so that a broad peripheral iridectomy is performed at the base of the iris. Too often, pulling up on the iris results in an iridectomy down toward or even into the pupil. By pulling the iris axially the ciliary portion of iris is excised to-

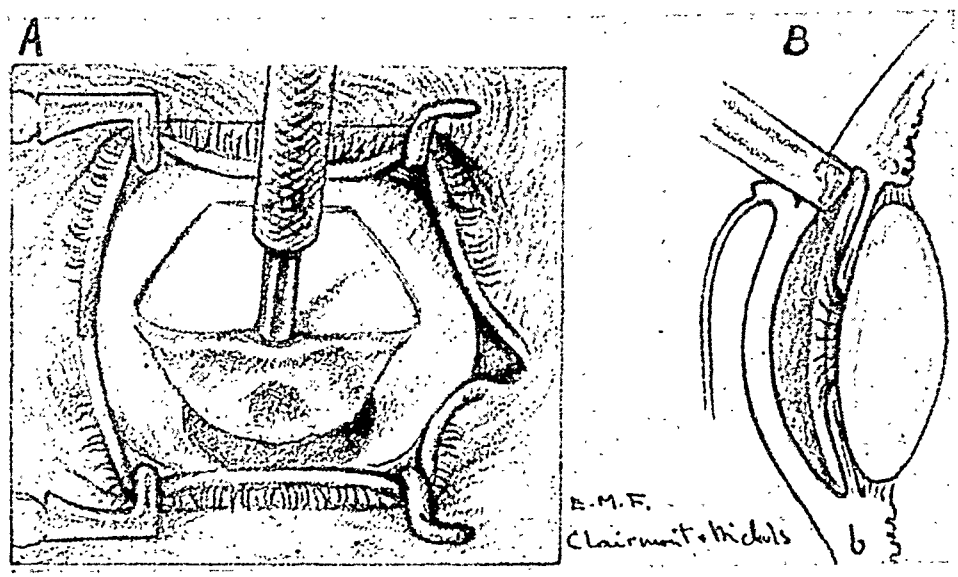

Fig. 10 (Meek). (A) A 1.5-mm. trephine is placed astride the corneoscleral margin. (B) The outer split half of the cornea acts as a shelf to hold the perpendicularly placed trephine.

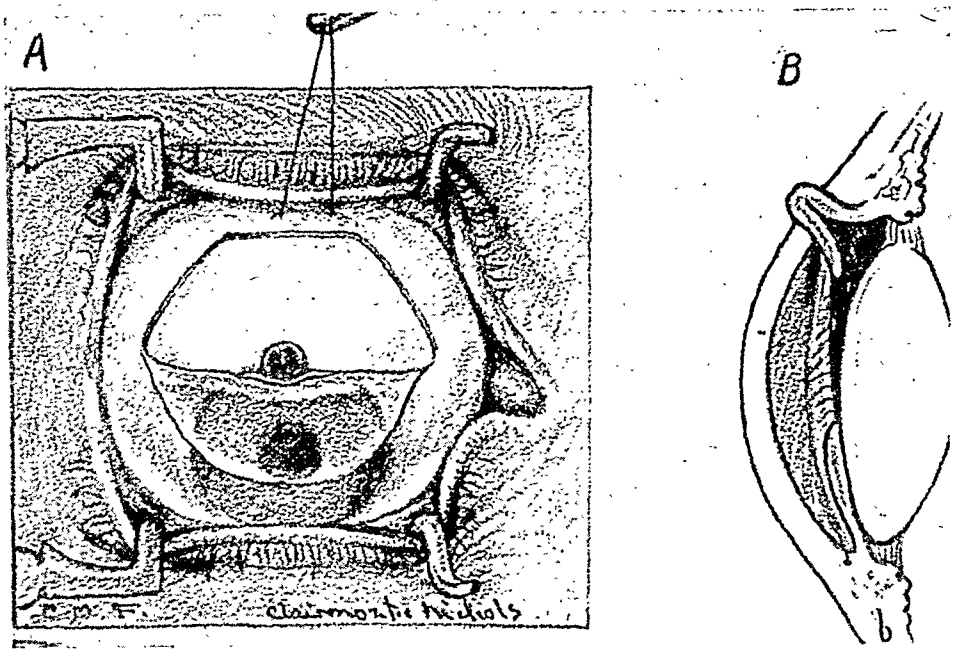

Fig. 11 (Meek). (A) and (B) The iris prolapses through the trephine opening.

gether with any ciliary processes which may be present on the iris. The iridectomy should be wide and deep because it may be surrounded on three sides by ciliary processes. The iridectomy should be sufficiently large to prevent its edges from touching the edge of the trephine opening when the pupil is dilated.

The corneoscleral plug is occasionally lost in the anterior chamber. This is of no consequence and the plug must be severely let alone. In at least two cases I have observed this plug lying on the iris without complications for several years.

If the iris tissue should remain in the opening after the iridectomy, it is easily dislodged by directing a stream of half-normal saline solution into the opening. This must

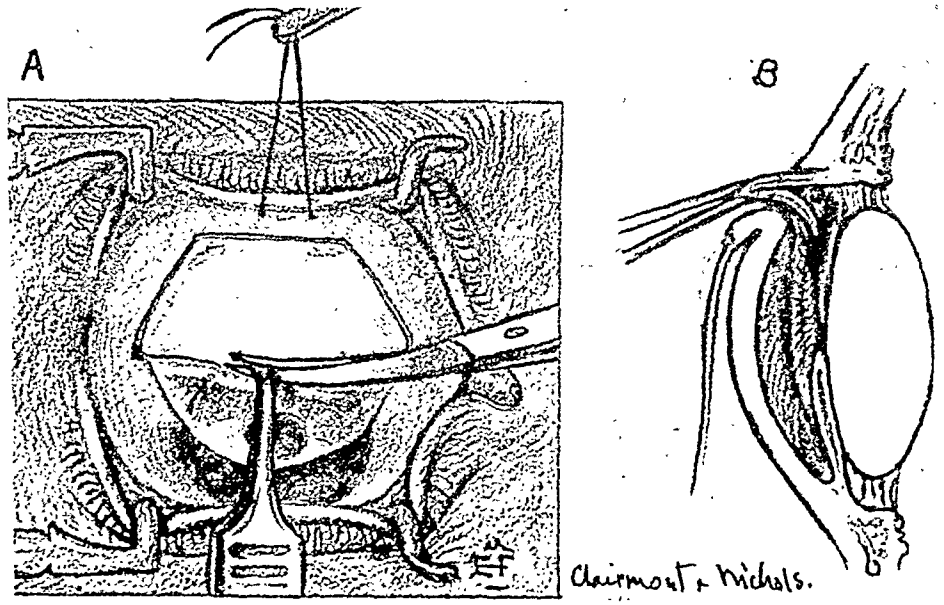

Fig. 12 (Meek). (A) The prolapsed portion of the iris is excised. (B) The iris prolapse is drawn down toward the pupil to get at the base of the iris.

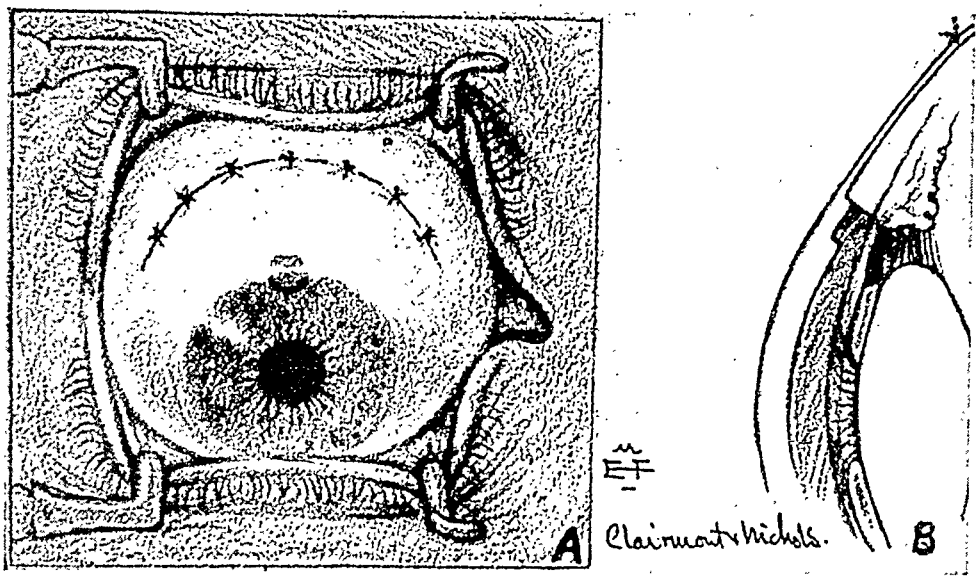

Fig. 13 (Meek). (A) The conjunctival flap with Tenon's capsule is drawn up and sutured. (B) Diagram to show the flap in relation to the trephine opening and why massage is necessary to keep the tissues separated.

be done at once and, if there is bleeding, before the blood clots. The trephine opening must be considered inviolable and no forceps or spatula should enter the anterior chamber.

If the iris does not prolapse, suction may be used, either a Dimitry suction with a lacrimal irrigator or a medicine dropper with a small tip. Disregard of this restriction may lead to damage to the lens, zonule, ciliary body, or anterior hyaloid membrane by misdirected instruments.

Payne[8] in examining enucleated globes in which trephining operations had been unsuccessful found the operative wound closed by dense connective tissue containing fragments of pigment, lymphocytes, and new blood vessels. Verhoeff[9] has described the perfect trephine wound as being filled with

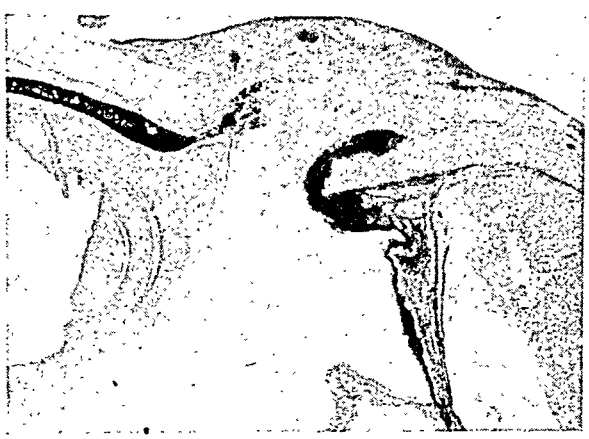

Fig. 14 (Meek). Ciliary process prolapsed into the posterior part of the trephine wound and iris tissue into the anterior part.

Fig. 15 (Meek). Ciliary process prolapsed into the trephine wound.

delicate connective tissue, full of empty spaces intercommunicating and traversing its extent and free of endothelium. Such a scar can be achieved only by keeping instruments and uveal tissue out of the trephine wound.

The toilet of the trephine wound being completed, the conjunctival flap is drawn up, smoothed back into its former position and the cut edges joined with a continuous plain catgut suture or a number 5-0 black silk suture.

In cases of chronic simple glaucoma with

no congestion or inflammation, a drop of ¼-percent eserine to draw the iris from the trephine wound is instilled. In an eye that shows congestion without definite iritis or

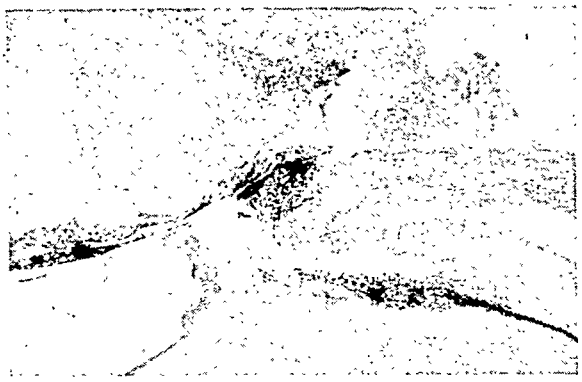

Fig. 16 (Meek). Iris in the trephine wound.

uveitis a drop of 2-percent pilocarpine is instilled. In glaucoma secondary to a uveitis, 1-percent atropine solution may be instilled at the time of operation or, better, at the first dressing especially when eserine or pilocar-

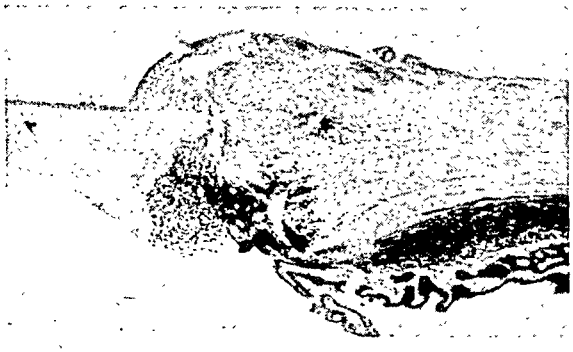

Fig. 17 (Meek). Iris in the trephine wound.

pine have been used. An ointment is applied to the closed eyelids to keep the lashes from sticking to the dressing. In my opinion it is a mistake to fill the conjunctival sac with ointment after any intraocular operation because of the danger of the ointment being drawn or forced into the anterior chamber. The eye is bandaged and may be observed in 24 hours.

A most important step of the operation comes on the third day when gentle massage is begun. This massage is done below the cornea to avoid additional trauma to the flap. The massage helps maintain the filtering

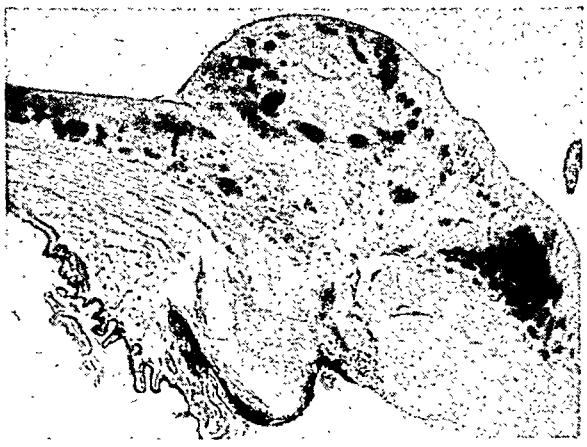

Fig. 18 (Meek). Iris lining the posterior portion of the trephine wound.

bleb and prevents the tissues covering and immediately surrounding the bleb from becoming firmly adherent to the sclera. This

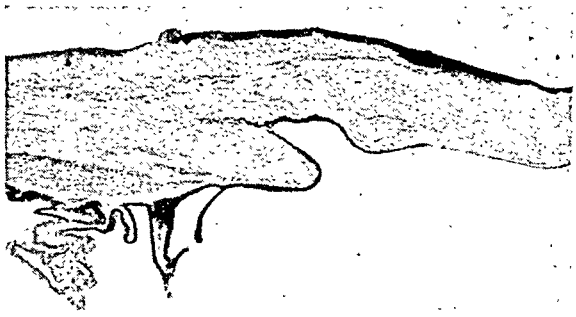

Fig. 19 (Meek). Iris in the wound.

massage should be instituted by the operator himself, for, if care is not used, an intraocular hemorrhage may occur. The massage is continued daily until the wound is healed and the circulation of aqueous established.

Although a filtering bleb is desirable and will usually be achieved by scrupulous technique, the bleb occasionally fails to form or disappears. Sometimes the bleb can be re-

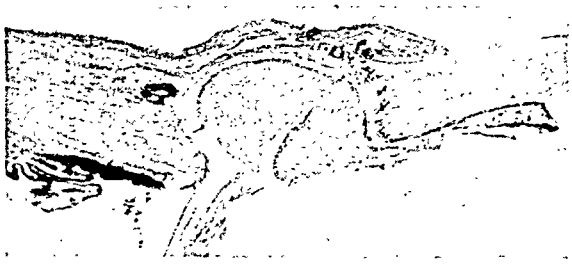

Fig. 20 (Meek). Iris and lens in the trephine wound.

stored by the injection of saline or air into the subconjunctival tissue. Absence of the bleb does not constitute a failure, for even in the absence of an apparent fistula the tension is reduced. Meller[10] states that he has found the tension reduced in 60 percent of such cases. This may be due to the peripheral basal iridectomy. A dressing is kept on the eye for a week.

Comments

From a study of pathologic slides I have found that the causes of failure of the Elliot trephining operation are:

1. The iris is found in the wound in most failures (figs. 14, 16-20).
2. Rupture of the lens with lens fibers in the wound (fig. 20).
3. Ciliary processes in the trephine opening (figs. 14 and 15).
4. Subluxated lens blocking the wound.
5. Hemorrhage.
6. Intraocular infection.
7. Episcleritis.

I have found more failures where iris tissue is caught in the wound than all the other causes put together. In all instances, the wound becomes filled with vascularized fibrous tissue. In every failure one of the above complications was found. The procedure suggested should go far to eliminate these complications.

Summary

A simple method of performing the Elliot corneoscleral trephining operation is hereby presented in the treatment of glaucoma.

Benedict's method of making the conjunctival flap to include Tenon's capsule is used. With a Wheeler or Lunsgaard knife an incision is made at the corneoscleral junction. The knife blade must be held perpendicular to the incision. The corneoscleral margin is sliced to one half its thickness. The cornea is now easily split to a distance of one millimeter. With the trephine placed astride the corneoscleral margin, and using the lower raised portion with its attached conjunctiva as a stop or shelf, the opening is made. The trephine should be held perpendicular to get a clean-cut disc or plug.

The iris tissue, which now presents in the trephine opening, is grasped near its base with iris forceps and, with slight tension pulling the iris toward the pupil, its base is excised. If no prolapse occurs, the iris may be withdrawn by suction.

The conjunctival Tenon's flap is replaced and sutured. Gentle massage below the cornea is begun after the anterior chamber has reformed (usually on the third day) and kept up daily until the wound is healed and the circulation of aqueous established. A dressing is kept on the eye for a week.

PSYCHOSOMATIC INTERRELATIONSHIPS IN OPHTHALMOLOGY

DAVID O. HARRINGTON, M.D.
San Francisco, California

With reference to psychosomatic medicine, it has been somewhat acetiously remarked that "any other brand of medicine is veterinary medicine."

Franz Alexander,[1] in a clarification of the question of psychogenesis, gives point to this statement when he says, "The distinctive feature of psychogenic factors such as emotions or ideas and fantasies is that they can be studied also psychologically through introspection or by verbal communication from those in whom these physiological processes take place. An automobile climbing a hill has no sensation of tiredness or of a goal to reach. In contrast to a man-built machine, the organism climbing a mountain has an awareness of certain of its internal physiological processes in the form of effort, tiredness, discouragement and so on. Moreover, man in contrast to the animal organism is able to convey these internal sensations to others by verbal communication. Verbal communication is therefore one of the most potent instruments of psychology and consequently of psychosomatic research. When we speak of psychogenesis we refer to physiological processes consisting of central excitations in the nervous system which can be studied by psychological methods because they are perceived subjectively in the form of emotions, ideas, or wishes."

OPHTHALMOLOGY AND PSYCHOSOMATIC MEDICINE

Ophthalmology as a medical discipline has not taken kindly to the concept of psychosomatic medicine. The past 20 years have shown revolutionary changes in the study and clinical application of psychology and psychiatry, but ophthalmologists have taken little or no advantage of these changes. They have, on the whole, either ignored this vital stream of new knowledge or have been downright hostile to its development. For example, when the late Dr. Mark Schoenberg[2,3] presented an extremely conservative paper on the therapeutic implications of psychosomatic interrelationships in glaucoma, in 1939, his work was greeted with reactionary jeers or "damned with faint praise" by most of the discussants. When I[4] published an article last year on "Ocular Manifestations of Psychosomatic Medicine," only 15 percent of the 200 requests for reprints came from ophthalmologists.

Perhaps there are several reasons for this attitude. As noted above, verbal communication is one of the most potent instruments of the psychologists. Words are to the psychiatrist what the stethoscope is to the cardiologist; and ophthalmologists are notoriously short on words. There is a precision of diagnostic and therapeutic procedure to ophthalmology which has encouraged too accurate particularization and has led to a conspicuous neglect of such evanescent qualities as psychic factors in ocular disease.

But the concept of psychosomatic medicine is in the ascendancy and its appeal will not be denied. It must be sympathetically studied and understood to be appreciated and no medical discipline can escape its imprint.

Dunbar's[5] very apt definition of psychosomatic medicine should especially appeal to ophthalmology, using as it does the idea of visual fusion. "Psychic and somatic represent merely two angles of observation. Our understanding of disease rests on pictures taken from these two angles viewed simultaneously, united stereoscopically."

In a summary of his views on psychosomatic research, Alexander[1] states that there are fundamental psychologic and physiologic differences between conversion symptoms, vegetative neuroses, and psychogenic organic disease. He suggests that we restrict

hysterical conversation phenomena to symptoms of the voluntary neuromuscular and sensory perceptive systems and differentiate them from psychogenic symptoms which occur in vegetative-organ systems, the functions of which are under the control of the autonomic nervous system.

A conversion symptom is a symbolic expression of a well-defined emotional content, an attempt at relief; although as Freud originally expressed it, these substitutive innervations never bring full relief. The symptoms express at the same time both the repressed emotion and its rejection. Because they do not fully relieve the tension, we have a pathologic condition.

A vegetative neurosis such as emotional hypertension is not an attempt to express an emotion but is the physiologic accompaniment of constant or periodically recurring emotional states. The chronicity of an emotional tension alone is what makes such a condition morbid.

Ocular disturbances of psychogenic origin

In considering ocular disturbances of psychogenic origin it would seem rational to divide them as follows:

I. Ocular conversion symptoms

1. Blepharopasm
2. Convergence spasm
3. Asthenopia
4. Photophobia
5. Hysterical amblyopia and amaurosis

II. Ocular vegetative neuroses

1. Ciliary spasm
2. Amaurosis fugax
3. Central angiospastic retinopathy
4. Migraine
5. Glaucoma

These are the more common ocular disturbances of psychogenic origin which will be discussed here. That there are others, I am aware, especially in the vegetative neurosis group. These will require further psychosomatic research for their proof.

Ocular phenomena of conversion hysteria

There is hardly a sign or symptom of organic disease which hysteria cannot simulate. While there have been many published articles on the subject of ocular hysteria, the majority of cases are diagnosed per exclusionem. After a thorough ocular examination has failed to reveal an organic cause for the visual loss, the condition is labeled "hysterical" by virtue of the purely negative result. Seldom is any attempt made to determine in a positive sense the existence of hysteria, an absolute necessity for both adequate diagnosis and rational therapy.

Blepharospasm

This symptom may vary from the transient "blinking" of a nervous child to the most severe and constant spastic closure of the lids. One of the most common of all ocular complaints in children, especially in the early school years, is a frequent, nervous "blinking" tic, which starts as a hardly noticeable increase in frequency of the normal wink reflex and becomes rapidly worse until it is noticed as an actual grimace by the parents or the school nurse. Many of these children are brought to the ophthalmologist for examination with this as their only symptom. In the majority of instances they are refracted and a pair of glasses prescribed in the hope that relief from a minor eyestrain will relieve the symptom.

It is true that an occasional case of this type will be found to have a considerable degree of uncorrected refractive error with secondary chronic conjunctivitis and consequent lacrimation and irritation leading to the development of the symptom, but in most instances the disturbance is purely psychogenic in origin. A careful history from the mother, with some sympathetic questioning and coincidental observation of the child, will reveal a background for conver-

sion hysteria of a mild character that can hardly be doubted.

The symptom may have started "after a severe scolding," "after a school-yard fight with a bigger boy," "after a severe fright by a dog." These are manifestations of a "shrinking from danger" where "squinting" or closure of the lids is a natural protective reflex. Often the symptom is first noticed when the child begins "audience reading" in school. The more difficulty the child has in learning to read, the more he stumbles and gropes for words, the more apt is he to develop obvious signs of anxiety, increased nervous tension, stuttering and stammering, and finally blepharospasm. This attempt at escape from a difficult situation is a typical example of a conversion symptom in hysteria.

From this mild form of "nervous tic," it is only the degree of severity and the duration of the hysteria which produce the elaborate muscular twitching of the orbicularis oculi and the grimacing spasm of the entire face that may finally result in the constant, spastic closure of the lids seen with relative infrequency in the adult.

To attribute these phenomena to eyestrain, refractive error, uncorrected phorias, and the like, as is frequently done, is manifestly improper. Even to make the diagnosis by exclusion of organic disease is a negative approach. One must, by proper psychiatric evaluation, establish the positive diagnosis of hysteria before treatment, if it is to be successful, can be based upon an exploration of the subconscious for an adequate explanation of the repression responsible for the symptom.

Convergence spasm

This is perhaps one of the most clearly defined ocular motor anomalies which may occur as a symptom in conversion hysteria.

Souders[6] reported a case of this type and briefly reviewed the rather meager literature. He states that the disturbance represents an excess of convergence usually associated with a comparable excess of accommodation which becomes pathologic because of its duration in a susceptible psychoneurotic patient.

In these cases, ample evidence of a psychogenic background is offered but again the diagnosis is made by exclusion of organic disease, and therapy by persuasion and counter suggestion is declared unsuccessful.

It is suggested that, in severe cases of long duration, one is not justified in pronouncing them incurable until all the possibilities of prolonged psychoanalysis have been explored. I have seen two cases of severe convergence spasm, associated with hysterical amblyopia, promptly cured by sodium-amytal narcosis followed by brief psychoanalytic therapy. Both were acute cases of short duration, and both were diagnosed by a positive psychologic approach to the hysteria rather than by negative exclusion of organic disease.

Asthenopia

This has become a waste basket of the eye symptomatology and has been used to describe everything from unclassified headache, photophobia, and eyestrain to amblyopia of psychogenic origin. Numerous articles have been written decrying the practice of prescribing glasses for eyestrain when an analysis of the patient's psychic background would have speedily revealed the real cause of his trouble.

Derby[7] believed that "ophthalmologists produce more neurosis than they cure. Too often the neurotic patient is dismissed with a minor change in his prescription, when what he really needs is a careful analysis of his condition and an explanation of how his various aches and pains should be interpreted and treated." Derby would like to see the word "eyestrain" banished from our vocabulary and states that "if the general public could learn that eyes are seldom strained, this would be a happier world to live in."

Rutherford[8] identifies asthenopia as a psychoneurosis "to distinguish it from simple eyestrain," and becomes considerably confused himself in the process. In the discussion which followed this paper, Lancaster called attention to the rule that a psychoneurosis should never be diagnosed on negative evidence alone.

Asthenopia, like all forms of conversion hysteria, is extremely susceptible to cure by suggestion but, only by being constantly alert and interested in the subject can the ophthalmologist avoid the common pitfall of temporarily curing a symptom while completely neglecting its cause. The prescription of a pair of glasses, no matter what their dioptic power, may result in immediate relief of eyestrain, headache, blurring of vision, and the like. Without a true analysis of the underlying cause and its treatment by psychotherapy, however, no more than a transient improvement, at best, can be expected.

Photophobia

In the absence of organic pathologic conditions, particularly intraocular inflammation and keratitis, the most common cause of photophobia is psychogenic.

Inman[9] states that "nearly every person who complained of glare or bright light, whether natural or artificial, had either definite fear of the dark or could remember his struggles to get rid of this fear when a child."

The complaint of photophobia was an extremely common one in the Armed Services during the war and has been reported by me.[10] It is usually a minor disturbance, frequently only a part of a more complicated conversion-hysteria symptom complex, but may reach such proportions as to be a disabling disorder in its own right. It is markedly increased by fatigue and by anxiety and emotional stress.

The exclusion of irreversible disease in severe photophobia is not difficult, but even more important in establishing the psychogenic origin of the symptom is a careful analysis of the patient's history and personality pattern. There is a frequent association of photophobia with blepharospasm, facial tic, and transient amblyopia from ciliary spasm. These associated symptoms and the photophobia itself can often be abolished by direction of the patient's attention away from his symptoms.

A typical example of severe and disabling photophobia was reported by me in the case of an aviation cadet who developed such anxiety over failure to pass his Morse code blinker-light signal test that, in an unconscious attempt to escape from an intolerable situation, he transferred his fear of failure to a fear of the light itself. When the psychogenic nature of the disturbance was understood by the patient, he was able to overcome his difficulty, qualified for advanced flight training, and the photophobia disappeared.

Hysterical amaurosis and amblyopia

There is a vast literature on the subject of hysterical blindness. The majority of articles, however, deal with individual case reports of hysterical amblyopia in which the diagnosis of the psychogenic nature of the disturbance has been made by the purely negative method of exclusion of organic disease. Many authors make reference to an "intolerable situation" as a factor in the production of the amblyopia, but almost none of them make any attempt to explore the nature of the psychic factors which alone will explain the raison d'etre of any individual case. Little attention has been paid by ophthalmologists to Freud's[11] comprehensive discussion of psychogenic visual disturbances in the light of psychoanalytic knowledge.

To quote Dunbar,[5] "To consider the numerous and peculiar ocular neuroses as disease entities is not permissible. It is not only that, in addition to the neurotic eye symptoms, there are always neurotic symptoms in other bodily spheres, but also that the neurotic symptom is always merely the ex-

pression of a psychic conflict in the total personality. It is with this total personality and its situation that we have to deal. Confronted with a neurotic amaurosis, we must deal, not with this, but with underlying disturbance in psychic equilibrium, if we are to understand the symptom and the necessary course of treatment. There is always a conflict out of which the neurotic individual finds no other way than that of flight into illness, which is itself an attempt at cure, even though unsuccessful. Persuasion and suggestion can at best eliminate a symptom. The deep sources of the neurosis are reached only by psychoanalysis."

It is not advocated that ophthalmologists should attempt to psychoanalyse their patients, but a study and appreciation of psychology is essential to intelligent coöperation with the psychotherapist.

Amblyopia is a much more common symptom of conversion hysteria than amaurosis. In the majority of cases in which the amblyopia is the dominant symptom, there are, however, other complaints and symptoms which can be readily uncovered by psychiatric evaluation and which fit into the picture of hysteria.

A recent article by Yasuna[12] reports 15 typical cases of hysterical amblyopia in men about to be discharged from the Army. All of the classical symptoms are demonstrated, including the resigned attitude of the patient to his disability; the slow, hesitant reading of the Snellen test chart, no matter what letters were chosen as minimum visual acuity by the patient; the typical tubular, sharp margined, visual fields found in almost all cases; and the marked amenability to suggestion resulting in rapid improvement in vision with only the most superficial psychotherapy.

Yasuna points out that while monosymptomatic hysteria is not uncommon, the greatest number of cases present a variety of manifestations and that the acute type in which the amblyopia develops suddenly is relatively uncommon. Most of the cases belong in the chronic groups in which no definite time of onset can be fixed; and the course is complex or of the mixed type, in which other elements of psychoneurosis are also present and frequently are the more obvious factors in the individual.

It is generally agreed that suggestion plays a most important part in the treatment of hysteria,[13,14] but it must be emphasized again that the transient "cure" of a symptom by suggestion is by no means a cure of the underlying psychogenic factors producing the symptom. Cure by suggestion, therefore, is of more value as a diagnostic procedure than as a rational form of therapy. Frequently, and especially in children, the complicated routine of a careful ocular examination carries so strong an element of suggestion that, during the procedure, the vision shows distinct improvement, and the correct diagnosis is thus established.

Lastly it must be remembered that the amblyopia of conversion hysteria may be superimposed upon a visual disturbance with an organic basis. I have recently established such a diagnosis in a patient with an extreme colloid degeneration of the choroid. The appearance of the fundus suggested the possibility of considerable loss of visual acuity, and the patient had been accepted as blind to the extent of receiving a large monthly pension and a seeing-eye dog. He had lectured before numerous groups on the opportunities and occupations open to the blind and was running his own successful dairy farm. His vision was reduced to light perception. Associated with his amblyopia, however, were other symptoms, such as severe photophobia and blepharospasm, strongly suggestive of the psychogenic nature of the disturbance. A careful psychiatric evaluation of the total personality of the individual revealed a pattern which left little doubt of the real nature of the disability. Improvement of vision to 20/20 with normal visual fields by suggestion and psychotherapy, further confirmed the diagnosis of hysterical amblyopia. The eventual cure of this pa-

tient's underlying psychoneurosis will be a most difficult problem. Cases of this sort demand the closest coöperation and understanding between the ophthalmologist and the psychiatrist.

Ocular vegetative neuroses

This is one of the most fertile of all fields for psychosomatic research. As noted above, a vegetative neurosis is not an attempt to express an emotion but is the physiologic accompaniment of a constant or periodically appearing emotional state.

There is ample anatomic and physiologic evidence of the cortical control of the vegetative nervous system through the hypothalamus.[31]

In a very comprehensive review of the experimental data on the anatomy and physiology of the hypothalamus, Ingram[15] conservatively concludes that the evidence clearly indicates that this portion of the brain contains important integrating mechanisms for the so-called vegetative functions. Many of these mechanisms produce their effects by influencing lower, subordinate complexes. In turn, the hypothalamus is undoubtedly under a certain measure of control by higher regions, including the cerebral cortex.

In a lengthy and well-documented article on hypothalamic function in psychosomatic interrelations, Grinker[16] concludes that "as a cephalic representative of the autonomic nervous system, the hypothalamus has to do with the energies of visceral origin which are the forces of the instincts."

Bard[17] was able to show conclusively that a central autonomic center resided in the hypothalamus and that there is also a direct inhibitory effect exerted on the hypothalamus by the cerebral cortex.

More recently Kennard[18] has correlated autonomic interrelations with the somatic nervous system and found that anatomic and functional interrelations between the autonomic and somatic nervous systems can be demonstrated at many levels; that emotions are known to produce responses in both autonomic and somatic nervous systems; and that these interactions take place chiefly within regions containing the extrapyramidal representation in the forebrain.

From an ophthalmic point-of-view all of this is simply evidence for the cortical or emotional control of the vasomotor system since most of the ocular vegetative neuroses are primarily vasomotor disturbances.

Ciliary spasm

This is, perhaps, the single exception to the foregoing statement. The action of the autonomic nervous system on the pupillary constrictor and dilator fibers and on the ciliary body is well known and has been reviewed by Cogan.[19] Many authors have called attention to the dilation of the pupils in both animals and human subjects under conditions of emotional stress, such as rage and fear.

Since the days of Helmholtz accommodation for far vision has been considered to be a passive process, the ciliary muscle being relaxed; while the accommodation for near vision is said to be an active process, the ciliary muscle being in a state of contraction.

Several authors have questioned the validity of this theory and Olmstead,[20] on the basis of careful animal experimentation, flatly states that "both divisions of the autonomic nervous system can act on the lens; that the influence of the sympathetic is in the direction of hypermetropia, and the parasympathetic in the direction of myopia; that there is a tonic action of both divisions of the autonomic nervous system, since removal of either leads to permanent dioptric change; that the radial fibers can act in groups; and that the same general picture resulting from sympathetic stimulation is shown in man as well as in lower mammals."

Relatively little has been written regarding the production of transient myopia by emotional disturbance such as fear or anxiety states, and yet it is a relatively common phenomenon and one which must be familiar to most ophthalmologists.[13]

The disturbance is limited to young people and manifests itself as a periodic and transitory blurring of distance vision usually associated with prolonged reading. There is often a sensation of ocular fatigue or even fairly severe pain and the visual loss may vary from slight to as low as 20/200, and may last from a few minutes to days or even weeks at a time. The change in refraction may vary from 0.50D. to as much as 2.0D. by manifest refraction and is characteristically altered by rest or by employment of the "fogging" method of refraction. The use of homatropine as a cycloplegic immediately abolishes or reduces the dioptric change, but this improvement is only temporary and the symptom becomes manifest as soon as the effect of the cycloplegic wears off. Ciliary spasm is differentiated from amaurosis fugax by the measurable change in the refractive power of the eye, but it must be remembered that both conditions may occur in the same eye.

A careful analysis of the histories of these patients will reveal a definite and sometimes severe anxiety state, and it is only by analysis of the psychogenic factor that a cure can be accomplished.

A typical example of ciliary spasm is seen in the young student who is on the verge of failure in school. Because of his poor scholastic ability he is forced to spend more than the average amount of time in study. His anxiety over his incipient failure causes him to work under more and more pressure until a vicious circle of more reading and greater anxiety results in a spastic myopia of greater or less degree.

I have found this disturbance quite frequently in medical students and it was extremely common in preflight and basic training schools in naval aviation in the last war. Here the consequences of failure, loss of the coveted wings and a commission in the Air Corps, had a correspondingly strong psychogenic factor.

Whether one adheres to the Helmholtz theory of accommodation or to the newer theories of dual autonomic innervation of the ciliary muscle does not alter the basic fact that this disturbance is a vegetative neurosis—the physiologic accompaniment of an emotional state.

Amaurosis fugax

This symptom complex differs from ciliary spasm in the absence of measurable dioptric change in refraction. It is a true vegetative neurosis which is vasomotor in origin and, as reported by me,[4, 21] differs only in the matter of degree of vasospasm from central angiospastic retinopathy, to be discussed later. It includes all those ocular disturbances, such as periodic dimness of vision and black out, which are associated with autonomic instability but leave no permanent or visible organic change. It is frequently a part of the symptom complex of neurocirculatory asthenia.

The chief complaint is of periodic visual loss which varies from transient fogging of vision to complete "black out lasting for 30 to 60 seconds and identical with the black out described by aviators at the termination or pull out of a power dive. The frequency and severity of the amaurosis may be so severe as to be actually incapacitating, but exhaustive ocular examination reveals no evidence of organic disturbance sufficient to account for the symptoms.

Even casual observation will reveal, in most cases, other evidences of vasomotor instability, notably an increased sweating of the hands, tremor of the fingers, and poor peripheral circulation with blanching of the fingers when the hands are held above the head and cyanosis when they are dependent.

Careful evaluation of psychogenic factors will always reveal marked anxiety state, frustration, fear, excitement, or homesickness, and treatment must be directed to these causative factors.

Central angiospastic retinopathy

This is the term applied by Gifford and Marquardt[22] to a type of macular retinal

lesion which they felt to be definitely of circulatory origin. They and Horniker,[23] Bailliart,[24] and I[21] have established evidence of general vasomotor instability in these cases and demonstrated the vasospastic etiology of the disease.

A large number of cases of central angiospastic retinopathy were reported in the Armed Services during the last war and I have seen a number of cases in the past year.

Visual disturbance is usually sudden in onset and may be quite severe with central vision reduced to 20/200 or less. The condition may be unilateral but is more frequently bilateral. Visual fields show a central scotoma of varying size and density. There is frequently a complaint of distortion of objects or metamorphopsia.

Examination of the fundi in the acute stage of the process shows a definite grayish edema of the macula with loss of foveal reflex and a generally smudged appearance of the macula. One of the earlier names for the condition was descriptive of this stage of the process—central serous detachment of the retina. As the edema subsides, the macula takes on a mottled, granular appearance due to redistribution of the retinal pigment. The absence of the foveal reflex persists. The vision may improve markedly but seldom comes back to its previous acuity.

A large number of cases show, in their final stage, a minute, sharply outlined, irregular hole in the fovea with a corresponding minute central scotoma and vision of 20/30 or 20/40. These macular holes are difficult to see but, with adequate illumination and especially with red-free illumination, they are usually quite visible when searched for.

In searching for the etiology of this condition, the only constant etiologic factor in nearly 100 cases seen by me[21] was autonomic instability and excessive stimulation of the vegetative nervous system. Practically all cases studied showed definite clinical evidence of vasoneurotic diathesis with hyperhidrosis, cyanosis or pallor of the finger tips, and deficient peripheral vascular systems as manifested by abnormal skin-temperature readings of fingers and toes.

Psychiatric studies have revealed almost uniform anxiety states, often of considerable severity. Even in peace time the psychosomatic aspects of the disturbance are quite evident to fairly casual study. Zeligs[25] has approached the subject psychosomatically and has pointed out the occurrence of anxiety as a common type factor in the production of central angiospastic retinopathy. It is realized that any autonomic stimulus of sufficient severity and duration can produce this condition but the most common stimulus is psychic trauma.

This is a classical example of a severe vegetative neurosis with associated physiologic disturbance of such intensity and duration as to become irreversible. The end result is an organic pathologic condition.

Migraine

While the visual disturbances associated with migraine are primarily cerebral in origin, the ocular symptoms are of so dominant a nature that a large percentage of sufferers first consult the ophthalmologist, and it is surprising how few ophthalmologists have a sympathetic understanding of the disorder or can even recognize its symptoms. A complaint of headache, if carefully analysed, will frequently reveal associated visual disturbance, slight or severe nausea, an aura which may vary from a vague sense of depression to an outstanding burst of physical energy, and a postheadache period of lassitude or mental sluggishness. These are the symptoms of migraine and they vary tremendously in intensity and duration. Further inquiry will almost always demonstrate a period of tension, anxiety, frustration, or other psychic trauma preceding each attack. The association of peptic ulcer with a migrainous history is too common to be mere coincidence.

I have observed two cases of severe migraine over a considerable period of time in which I could easily demonstrate visible

vasoconstriction in the retinal arterioles during the aura preceding the attack and continuing on into the period of preheadache hemianopia. In numerous other instances I have found overwhelming evidence of emotional disturbance and I am completely in agreement with Wolff's[26] observation that subjects with migraine show certain typical personality features and reactions. It has been my observation that most migrainous patients show strong evidence of a vasoneurotic diathesis. Most of them are overly conscientious. They accept responsibility but only at great cost to their peace of mind. They often suffer from insomnia. The incidence of migraine is greatly increased during periods of stress, notably during the last war.

It is now, I believe, generally accepted that migraine is a vasospastic disorder; that the preheadache scintillating scotoma and homonymous hemianopia occur as the result of a severe cerebral vasospasm, and that the compensatory vasodilation produces the headache.

Even the somatists, with their elimination diets, have come to feel that the allergic reaction is a vasomotor one, and those who are using the trypan-red, vital, staining-dye method of treatment concede that its action is to lower vasomotor tone.

Psychiatric treatment of migraine subjects is admittedly difficult but, if the condition is recognized as a vegetative neurosis, much progress will have been made toward its relief.

Glaucoma

This is one of the most fascinating of all subjects from the standpoint of psychosomatic interrelationships in ophthalmology.

The importance of the psychic factor in glaucoma is recognized by every ophthalmologist. Many authors[2, 3, 27, 28] have cited instances of psychic precipitation of single attacks of acute glaucoma and almost every ophthalmologist can duplicate these case histories from his own records.

If it is assumed that attacks of acute glaucoma may be precipitated by psychic shock, is it not also possible, as suggested by Sussmann,[29] that the latent disposition toward glaucoma has its causal basis in the unconscious life?

More and more evidence is being accumulated to show the close relationship between the intraocular vascular circulation, the secretion of the intraocular fluid, the level of intraocular pressure, and their control by autonomic nervous system.

As has been pointed out above, our present knowledge of the anatomic and physiologic connections of the autonomic nervous system with the higher cerebral centers through the hypothalamus makes it logical to assume a direct effect on intraocular pressure by these higher centers. Certain it is that there are many aspects of glaucoma which cannot be explained by the purely mechanical theories of aqueous drainage.

In an extremely interesting recent study of personality patterns in 27 selected cases of primary glaucoma Hibbeler[30] has demonstrated that more than two thirds of the patients showed marked deviations on one or more of the personality scales as measured by the Minnesota Multiphasic Personality Inventory. In many instances, the personality deviations were so severe as to suggest behavior bordering on the psychotic.

Schoenberg[2, 3, 31] contended that the eyes of some patients with glaucoma registered states of anxiety which acted as a precipitating factor for the development or maintenance of a high intraocular pressure. He argued from this that some of the glaucomatous crises are therefore preventable by proper attention to the patients' emotional life. He stated that ophthalmologists must familiarize themselves with the fundamentals of psychoanalysis and psychotherapy and must become interested in the personality problems of their patients, and that a somatic diagnosis without a survey of the patient's emotional life is an incomplete diagnosis.

I am in complete agreement with these statements of Dr. Schoenberg, although I believe he was somewhat conservative in limit-

ing his thesis to the precipitation of glaucomatous crises in previously glaucomatous eyes by anxiety states. It is my belief that chronic emotional disturbances may play a definite part in the progress of a primary glaucoma without reference to congestive failure or crisis.

For this view I anticipate criticism and repeat my statement from an earlier paper,[4] "It is not my purpose to advocate the thesis that glaucoma is a purely psychosomatic disorder or to prefer psychotherapy over all other forms of treatment in glaucoma. I feel, however, that psychic trauma may be an important causal factor in many cases of glaucoma and that its recognition will lead to a more rational and complete therapy of the disease."

Summary

Ophthalmologists have not appreciated or availed themselves of the recent advances in psychodiagnosis and psychotherapy as they apply to their specialty.

The fundamental differences between conversion symptoms and vegetative neurosis are discussed.

The following ocular disturbances of psychogenic origin are described and discussed.

I. Ocular conversion symptoms
1. Blepharospasm
2. Convergence spasm
3. Asthenopia
4. Photophobia
5. Hysterical amblyopia and amaurosis

II. Ocular vegetative neuroses
1. Ciliary spasm
2. Amaurosis fugax
3. Central angiospastic retinopathy
4. Migraine
5. Glaucoma

384 Post Street (8).

THE INFLUENCE OF TORSIONAL MOVEMENTS ON THE AXIS OF ASTIGMATISM*

STEFAN VAN WIEN, M.D.
Chicago, Illinois

A number of recent publications[1-3] dealing with changes of the axis of astigmatism have aroused new interest in this problem. These changes concern either those resulting from effort to maintain fusion for distance or those brought about by convergence. The present investigations were undertaken with the former changes in mind, and a simple method of examination will be suggested. However, in order to evaluate this problem in its true perspective, it seems appropriate to scrutinize the complex mechanism of torsional movements of the eyes. Only by recapitulating the physiologic principles involved is one able to draw any conclusions as to the importance of the relatively small part that the abnormalities in question play.

A number of coördinated movements of the eyes that can be performed voluntarily can be differentiated. There are two main groups, the conjugate and the disjunctive movements. To the former group belong levo- and dextroversion, elevation and depression; to the latter, convergence and divergence. A number of movements should be added that can be performed under certain conditions only, and that cannot be called voluntary per se: Abduction and adduction (or prism divergence and convergence), and supra- and infraduction (sursum- and deorsumvergence). All these movements can be performed from the primary position. Rotations around the transverse axis involve the "angle of altitude," those around the vertical axis are relative to the "angle of azimuth." Movements around these axes are referred to as "cardinal movements," and the positions reached as "secondary positions." The eyes are not restricted to cardinal movements, and can be rotated in any oblique meridian. But, in any event, they will have to rotate around an axis that is perpendicular to the line of fixation, as formulated in Listing's law: "When the line of fixation passes from its primary to any other position, the angle of torsion of the eye in this second position is the same as if the eye had ar-

*From the Department of Ophthalmology, Northwestern University Medical School. Aided by a grant from B. Spero for the Sanford R. Gifford Memorial Fund.

rived at this position by turning about a fixed axis perpendicular to the initial and final positions of the line of fixation."[4] The term "torsion," as used by Listing needs clarification: It does not indicate any actual rotation around the anteroposterior axis but rather a position of the globe. Peter[5] suggested "false torsion," a name that does not help to clarify the situation.

True torsions, that is rotations around the anteroposterior axis, are, of course, of extreme interest in connection with the problem under discussion. It is obvious that if such a rotation should take place, and the eye happens to be corrected for astigmatism, the axis of the astigmatism that coincides with that of the cylinder in the primary position will assume an angle after it has performed a wheel movement. Theoretically two types of movement are possible: A conjugate form if both globes rotate in the same direction, and a disjunctive form if they rotate in opposite directions. Neither one of these movements can be voluntarily performed from the primary position.

There are three ways to induce torsional movements:[6] The most obvious, static-dynamic procedure—that is, turning of the head—is not suitable for experimental work. Obviously tilting of the head not only causes rolling of the globes around the anteroposterior axes; it also calls for compensation of a vertical imbalance created by this type of movement. Besides, only conjugate torsion can be produced, and the disjunctive rolling that is most important in connection with our present investigation cannot be induced in this manner.

A second method is to create torsion optokinetically. This means was employed by Brecher,[6] who had the subject observe rotating wheels that were provided with alternating white and black sectors in a haploscope. Up to a certain speed, and for most observers, a rotary nystagmus was produced similar to horizontal nystagmus elicited by a drum provided with black and white vertical stripes and rotating around a vertical axis. If the speed of the wheels exceeded a certain maximum, the torsional movement of the eyes became sustained. Depending on the direction of the rotation of the two wheels, the rotary nystagmus—and torsion—was either conjugate or disjunctive.

The method most frequently used to study torsional movements, however, is through actuation by optical means. Most frequently one or the other modification of the haploscope is used.[7-11] Helmholtz[12] described a rather ingenious device to cause rotation of objects. Two right-angle isosceles prisms are held in front of one eye in such a manner that the surfaces of the hypotenuse are parallel but in opposite directions. Since objects viewed with such an arrangement undergo a double inversion (left to right by one prism, and vertical inversion by the other) they appear in an unaltered position. If the two prisms are rotated around their common axis, an apparent rotation can be effected. Helmholtz was able to compensate for a rotation of up to 7 degrees. The most recent, and at the same time the most accurate, investigations have been undertaken by Ogle and Ellerbrook[13] by means of the space eikonometer.

The idea that prompted all these investigations was to determine in the interest of binocular vision whether the eyes would follow any rotation that the objects underwent. If such vision is maintained, this may be due to fusion without any torsional movements of the eye, or the eyes may execute the same amount of torsion as the object viewed. A third possibility is a combination of the two: The torsion of the eyes lags behind the rotation of the objects, and the difference is supplied by fusion.

In the first instance the image points would have to fall on corresponding areas of both retinas. Corresponding retinal areas are a function of two lines: The horizontal line of separation (Ruete) or the horizon of the retina (Helmholtz), and Ruete's vertical line of separation (Helmholtz' apparent vertical meridian). It is only necessary

to state the longitudinal and latitudinal deviation in order to express the exact position of any point on the retina. If the two positions are identical, the retinal points are corresponding; otherwise they are disparate (Fechner). It should be recalled that the torsional movement would take place to fuse the two vertical lines in (a) the two horizontal lines in (b) should include an angle. Actually they form a continuous line as in (c).

No torsional movement is necessary for this effect but fusion of the disparate points

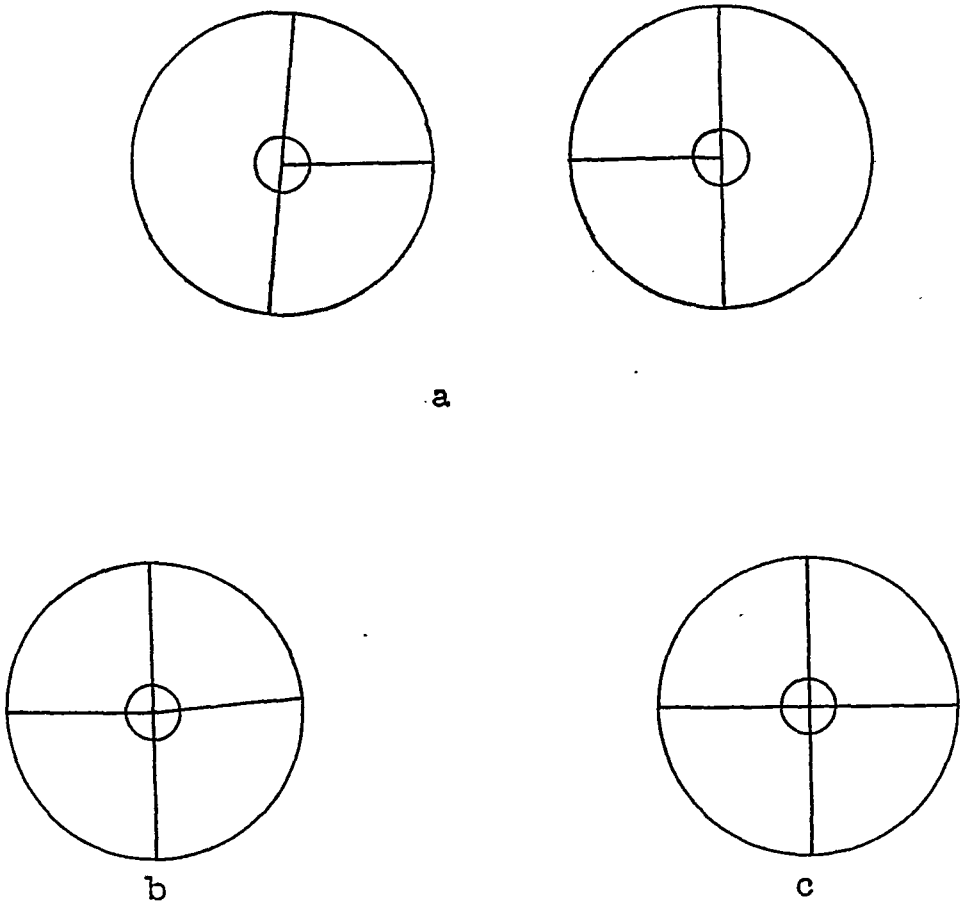

Fig. 1 (Van Wien). Fusion of the two circles in (a) will result in one vertical and one horizontal straight line (c). The vertical line declines forward. This is due to cyclofusion of the two vertical lines and not due to cyclotorsion which would result in an angulation of the horizontal line (b).

vertical lines of separation do not coincide with the geometrical vertical line: The upper ends tilt outward from 0-1° 30′.[14] The only plausible conclusion that can be drawn from this fact is that, in most instances, it is impossible for all points on a vertical line to fall upon corresponding points of the two retinas. Most investigators seem to agree that the eyes actually perform cyclotorsional movements.[7-9,11-13,15-16] Verhoeff[17] in his earlier publications doubted that cyclotorsion actually occurred. He argues that if (fig. 1), of the two vertical lines will result in one single line. It should be noted that the declination of the two vertical lines impresses stereoscopically as an inclination; that is, the upper part appears to be closer to the subject. An even stronger argument was introduced by Verhoeff when he pointed out that cyclotorsion could not possibly account for fusion in the case of the two curved lines illustrated in Figure 2.

Again, the resulting single vertical line can only be explained as being the product of

fusion of disparate points and, consequently, a stereoscopic illusion prevails.

Years later, Verhoeff[10] repeated Hofmann's and Bielschowsky's[11] experiments. There was a modification in the setup, but he employed printed texts as objects, and, this time, he reached almost complete agreement with their conclusions. He considered cycloduction a normal function of the eyes but took great pain in emphasizing that single or multiple lines accord but a feeble stimulus to cycloduction. Printed words are much more effective, and this was the reason why he could not convince himself in his earlier work of the existence of this phenomenon. His maximum range of eso-cycloduction (printed words serving as a stimulus) was 5 degrees, the maximum range of exo-cycloduction was about 4.5 degrees. This contrasts with 20 degrees mentioned by Hofmann and Bielschowsky. What seems to be most significant, Verhoeff was able to demonstrate that maximal cycloduction is always less than the angular deviation of the stimuli required to produce it. It was already noted by Nagel[7] that wheel motions do not exceed 5 degrees for each eye (a total of 10 degrees for both eyes). Ogle and Ellerbrook again report that the torsional movements of the eyes can, to a varying extent, lag behind the angular deviation of the object. According to Hofmann and Bielschowsky, vertical and torsional compensation is relatively slow as compared to the very rapid abduction and adduction. In other words, if cyclofusional movements lag behind the angular deviation at first, they may be rather complete after a certain time interval. Both eyes participate in the rolling, even if the object is rotated for one eye only (Hering).

To summarize, and in answer to our original question, it can be stated that angular displacement of objects can be compensated for by all three possible means; that is, no cyclotorsion at all, only partial cyclotorsion, or cyclotorsion to the exact extent of the angular displacement of the object. Whereas, in the first two instances fusion of the disparate retinal points will guarantee single vision, in the last instance the retinal images will fall on corresponding points. Fusion of disparate retinal points will give rise to stereoscopic vision. It should be remembered, as Ames[9] has pointed out, that only vertical diameters go into perspective. While the human brain has the capacity to interpret noncorresponding retinal areas along the vertical diameter as fused, if they can be interpreted as a single object in perspective, the fusion of rotated horizontal diameters is based on what he calls "corresponding fusional sectors."

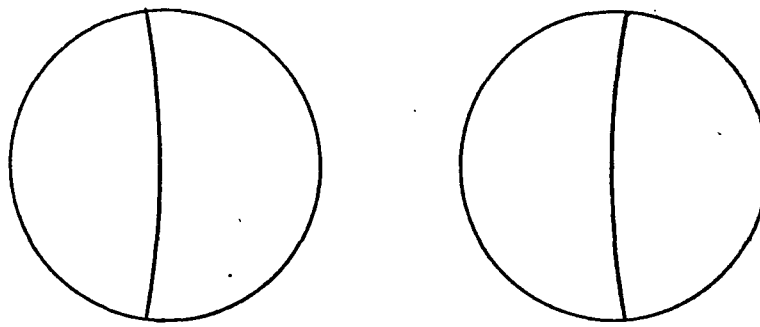

Fig. 2 (Van Wien). Fusion of the two curved lines to produce an image of a single vertical line convex to the observer is entirely possible but cannot be explained by torsional movements of the eyes.

The torsional movements discussed so far are forced and unnatural. They can be produced by special arrangements only. It has been necessary to discuss them in order to understand more clearly those that do actually occur under physiologic conditions:

Compensatory movements in instances of cyclophoria and torsions encountered in deviations from the primary position of the globes.

Savage,[18] in his original report in 1890 on what Price later called "cyclophoria," spoke of "insufficiency of the obliques." Although he deserves full credit to recognize this syndrome first, his explanation is based on false premises: A weakness of an oblique muscle would not only result in cyclo- but also hyperphoria.[19] Also, his statistics as to the occurrence of cyclophoria in 25 percent of cases during convergence as an anomaly is open to discussion,[20] and will be dealt with later.

Cylcophoria usually is not included in routine tests for muscle imbalances. This may have two reasons: Firstly, there is no satisfactory treatment for this anomaly; secondly, no treatment is indicated since cyclophoria, usually, does not cause any symptoms. There are two noticeable exceptions to this rule, namely the combination of cyclophoria with high degrees of astigmatism, and "pseudo-cyclophoria" (Savage) that is induced by oblique astigmatism. Peter[21] prefers to call the latter "accommodative" cyclophoria in order to harmonize with terms applied to other subdivisions of heterophoria. This type, accommodative cyclophoria, is considered first.

For an eye suffering from oblique astigmatism or one that has been made astigmatic by a cylindrical lens at an oblique position, the image focused on the retina will lean toward the maximal corneal meridian. In Figure 3a, a cross is formed by a vertical and horizontal line. Let this cross be viewed by a right eye through a strong minus cylinder at axis 135°. Both the vertical and horizontal lines will lean toward the axis of the cylinder, resulting in a displacement illustrated in Figure 3b.

This phenomenon was first described by Maddox.[22] Its explanation seems fairly obvious. In the cited instance the eye has been made hyperopic in the 45-degree meridian (it requires a plus cylinder to correct the minus cylinder at axis 135°). With the 45-degree meridian positive, the 135-degree meridian is relatively negative. Along the 45-degree meridian, therefore, the refractive power of the eye has the effect of a plus lens, and any object point not coincident with this 45-degree meridian is subject to prismatic displacement. The vertical as well as the horizontal line in Figure 3a increase their distance from the effective power of the meridian toward the periphery. According to Prentice's rule, both lines will undergo a continuously increasing displacement away from this 45-degree meridian. The negative principal meridian at 135-degrees, on the other hand, has the opposite effect, that of a prism with the apex along its course, and will displace the vertical and horizontal lines toward it, thus in-

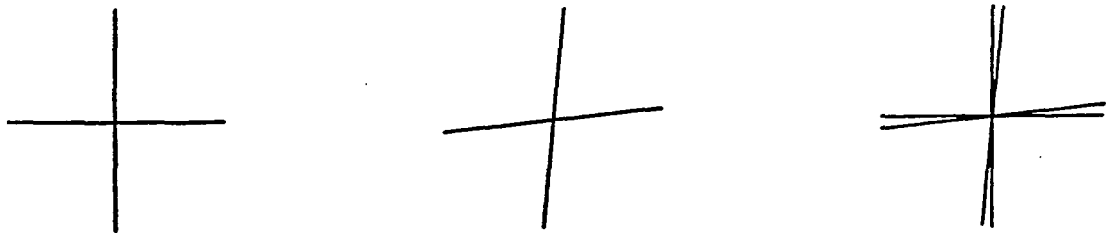

Fig. 3 (Van Wien). A true 90-degree cross as in (a) appears to an astigmatic eye as a skewed cross as in (b); if superposition without fusion could occur, the resultant image would be that of (c).

tensifying the action of the positive principal meridian. In binocular vision, and with the left eye emmetropic, the superimposed retinal pattern will appear as in figure 3c, that is, the two retinal images will not fall upon corresponding retinal points. What is more, they cannot be made to coincide simultaneously by wheel motion. According to Maddox, either intorsion will be necessary to bring the vertical lines into the same position, or extorsion to guarantee the same result for the horizontal lines. This explanation has been accepted by the majority of authors.

Only Verhoeff[10] has pointed out that coincidence could be obtained by fusion instead of wheel motion. His reasons have been given earlier in this paper. It is easy enough to determine what happens if Figures 3a and 3b are brought together by fusion: It is impossible to fuse the horizontal lines (unless they are very short, and include a very small angle). The vertical lines can be fused quite easily but the upper end of the fused line will appear tilted forward. This should prove beyond the question of a doubt that this fusion is not brought about by a cyclotorsional movement that would bring corresponding retinal points to coincide. In that case, no stereoscopic illusion would prevail. Only fusion of disparate retinal points will bring about such a result.

It is easily possible to repeat Hofmann's and Bielschowsky's experiments (they also formed the basis for Verhoeff's later investigations) without any special arrangements. With very little practice one can learn to suspend convergence, and fuse identical or nearly identical objects without the aid of a haploscope. Two squares containing the same text are brought into a position where it is possible to fuse them. If these two squares are rotated slowly in opposite directions (either toward or away from each other), single vision can readily be maintained. The motion has to be slow, and only 2 or 3 degrees at a time. If each of the squares is marked with a cross in identical position, there will be only one cross and, after fusion is maintained for a few seconds, no stereoscopic effect will be perceived. This, then, would indicate true wheel motion, that is the two crosses fall upon corresponding retinal points (fig. 4).

The same experiment is now repeated, this time with the two lines forming one cross being declined as it would appear to an astigmatic eye. If the two squares are rotated

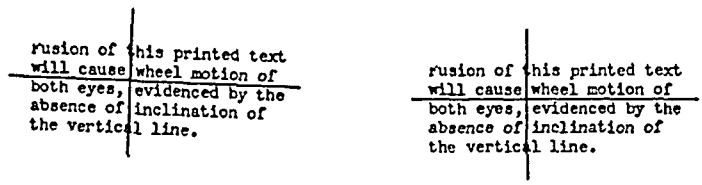

Fig. 4 (Van Wien). This would indicate true wheel motion—the two crosses fall upon corresponding retinal points.

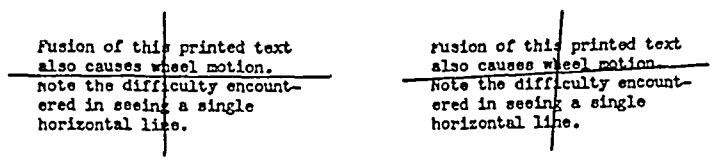

Fig. 5 (Van Wien). If the two squares are rotated toward each other, and the torsion of the two eyes lags somewhat behind that of the targets, the vertical lines will fall on corresponding, or nearly corresponding, retinal areas, and there will be no stereoscopic illusion with regard to these lines.

toward each other (fig. 5), and the torsion of the two eyes lags somewhat behind that of the targets (as is the case, according to Verhoeff), the vertical lines will fall on corresponding, or nearly corresponding, retinal areas, and there will be no stereoscopic illusion with regard to these lines. The horizontal lines are within Ames's "fusional sectors," and, consequently, will be seen singly but not in perspective. Similarly, in extorsion only the vertical lines need actual fusion. However, in that case, inclination of that line will be noted.

For practical purposes, the "induced" type of cyclophoria does not represent any therapeutic problem at all: Correction of the astigmatic error will eliminate it. The combination of astigmatism and essential cyclophoria introduces a different problem. Routinely, the axis of astigmatism is determined monocularly. However, a wheel motion will take place during the act of binocular vision causing a discrepancy between the axis of the astigmatism and that of the correcting lens. It was this problem that prompted the present investigation. A method to correct this form of "induced" cyclophoria will be suggested later.

In dealing with positions other than the primary, it is necessary to consider conditions prevailing during convergence. Hering,[23] prompted by studies of Meissner, v. Recklinghausen, Volkmann, Helmholtz, and Donders, demonstrated that Listing's law does not apply to positions reached in either symmetrical or asymmetrical convergence. Rather are the vertical meridians declined further outward, or, respectively, less inward in symmetrical positions of convergence than is required according to Listing's law. This deviation increases not only with the increase of the angle of convergence but also with an increase in the depression of the visual plane and in extreme instances reaches almost 5 degrees. In asymmetrical convergence that amount of torsion is very similar to that resulting from equally strong symmetrical convergence. Rarely is there a divergence of the lower ends of the vertical meridians.[24] A striking way to demonstrate this phenomenon is by the following three experiments:

1. With a pencil held vertically but below the level of the eyes, and with this pencil viewed by depression of the eyes without corresponding movement of the head, diplopia can be produced by relaxing convergence. If the two images are then allowed to fuse slowly, it will be noted in most instances that the lower ends touch first, forming a V. Only as fusion is completed will the upper ends touch, resulting in one single pencil in exactly vertical position.

2. If the pencil is held as described, but the depressed vision obtained by head movement, the phenomenon just described is likely to occur but with a decrease in the angle between the two images.

3. If the pencil is, however, held in the vertical plane whether at eye level, or below eye level with depressed vision obtained by head movement, then the declination cannot be observed, and the two images will appear parallel and approach each other in that manner.

This form of cyclotorsion should be considered physiologic (perhaps in the same light as exophoria for near). While undoubtedly cases may exist that are of pathologic origin, as some of those reported by Hughes,[2] it would seem that most of the cases included in Sugar's[3] series are of the physiologic variety. This type of cyclotorsion should hardly ever give cause to visual discomfort because, as mentioned before, it depends not only on the angle of depression of the visual plane but also on the angle that the visual lines form with the plane of the object, and will be minimized if they form a right angle. It is reasonable to assume that the subject, in the process of reading, will instinctively hold the reading material in the most favorable position.

Conjugate torsion of the eyes, as a compensatory movement to the tilting of the head, was denied by Helmholtz,[25] provided

the position of the line of fixation relative to the head remained unchanged. In commenting on this statement by Helmholtz, v. Kries[26] in his notes cites Javal, A. Nagel, Mulder, Skrebitzky, Woinow, Donders, and W. Nagel, all of whom proved the actual existence of such a compensatory mechanism. However, it "amounts to only a small fraction of the inclination of the head. This fraction which is compensated by the opposite rolling of the eye is about one-fifth when the rotations are slight, and gets as low as one-tenth when the rotations are considerable.*"

Depending on the amount of astigmatism, even such a slight discrepancy between the axis of astigmatism and that of the correcting lens must lead to considerable blurring of vision. Glasses, of course, will exactly follow the tilting of the head. For all practical purposes, however, this condition will hardly ever give rise to any discomfort because, under ordinary conditions, the head is not inclined but held in an erect position.

From the discussion thus far it should have become evident that the only instance where a shift of the axis of astigmatism is of importance is when it occurs in connection with essential cyclophoria. These cases are met with not too frequently; nevertheless, ever so often, a patient with strong cylinders will obtain excellent vision monocularly but complain of blurring or tilting of objects after he receives the new correction. It is this type of case that should benefit from an examination under binocular conditions.

Method

A sheet of polaroid filter is used to cover half of the smallest line that can be read with ease on the visual-acuity chart. Another polaroid film is mounted between two thin glass plates in the frame of a trial lens. It is easy to determine that position of the trial lens that blacks out the portion of the visual acuity chart that is covered. The vertical or horizontal axis of that position is marked on the trial lens. It can be inserted in the trial frame with the patient's correction. To insure proper alignment it is preferable to use a phorometer or phoropter. With the polaroid lens in front of the eye not under investigation, binocular vision is guaranteed. At the same time, this eye cannot see the small area that the eye to be examined observes. Copeland[27] has suggested to use a strong plus lens to obtain the same result. However, with Copeland's method, if the lens blurs the vision sufficiently, there is no stimulus for binocular vision and, therefore, the method outlined here may prove superior. The eye not examined, and with the polaroid lens in place, is screened by an opaque cover, and the axis of astigmatism determined carefully with the cross cylinder. Next, the screen is removed and the axis determined again, this time under binocular conditions. Any shift in the axis of astigmatism thus will become evident. This procedure is repeated for the other eye.

Since a combination of cyclophoria and high astigmatism causing clinical symptoms is not too frequent, a series of patients that showed astigmatism of 1.5 diopters or more was chosen at random. In addition to determination of the axis of astigmatism under binocular conditions, a test for cyclophoria for distance only was performed with two Maddox rods in vertical position. The two horizontal streaks of light were separated by 8 prism diopters of vertical prism evenly distributed between the two eyes.

Results

A total of 46 patients were examined. It was felt that, if the cylinders were below a certain strength, slight changes of the axis would be too insignificant to be appreciated; 1.5 diopters was, therefore, chosen as the smallest cylinder. Most cases were considerably higher, the average being 3.61D. Twelve

* It is a daily experience of every refractionist that patients try to correct a wrong axis by tilting the head. Only a compensatory rolling of the eyes can succeed in altering the relation between the axis of astigmatism and that of the cylinder.

patients had astigmatism of 1.5D. or more in one eye only. In these cases, only the eye with the high cylinder was examined. The other eye was neglected, and was not included in determining the average strength of astigmatism.

In 39 cases no variation in the axis of either eye was shown; neither was there evidence of cyclophoria. Among three cases, cyclophoria of 2, 2.5, and 4 degrees could be demonstrated. In these, the axes remained unchanged during binocular examination. Two cases showed a shift in the axis of one eye of 5 degrees and 15 degrees respectively. The strength of astigmatism in the first instance was 1.5D. in the second 2.0D. In one case, the right cylinder of 3.75D. shifted from 15 degrees monocularly to 8 degrees binocularly. The left cylinder of 3.0D. changed from 165 to 170 degrees. This was a disjunctive rolling as could be expected in compensation for cyclophoria. No such anomaly could be demonstrated. Only one patient had a cyclophoria of 2.5 degrees in the left eye (there definitely was no tilting of the right eye when tested with the Maddox rod), and a shift of 5 degrees of the left axis during binocular test. The strength of astigmatism of that case was 4.0D.*

Summary and Conclusions

In evaluating the importance of torsional movements of the eyes it is necessary to examine first those that are forced by experimental methods. They can be produced optokinetically, or by optical means—that is, by prisms—a method suggested by Helmholtz, by various modifications of the haploscope, or by the space eikonometer. It can be stated at present that rolling movements of the eyes do result under such arrangements. However, the amount of rolling does not necessarily have to equal that of the targets employed, and, at its maximum, does not exceed 5 to 10 degrees. If no strong stimulus for fusion is present—that is, a printed text—cyclofusion may take the place of cyclomotion. Unless the torsion of the globes equals that of the targets, a stereoscopic effect in the form of inclination will be observed.

From the clinical point of view this type of wheel motion is of no importance as it does not occur under physiologic conditions. However, a number of problems are met with by the refractionist in his daily routine that should be clearly understood. All these problems have in common the correction of astigmatism since, obviously, a cylindrical correction cannot follow torsional movements of the eyes. Fortunately, the one anomaly that has to be dealt with most frequently, namely cyclophoria induced by astigmatism "off axis," does not present any problem at all: The correction of the astigmatic error simultaneously eliminates the necessity for overcoming the induced cyclophoria. If uncorrected, this anomaly is all the more annoying because the vertical and horizontal axes are not displaced in the same direction but toward each other thus making virtually impossible compensation by actual torsion; this is responsible for the headaches caused by the continuous effort of cyclofusion.

Torsional movements of the eyes with an accompanying shifting of the axes of astigmatism have been observed to occur as a result of changing fixation of distant objects to those at reading distance. This fact is not so much due to convergence as to the depression of the visual axes that occurs simultaneously. If the line of fixation and the plane of the reading matter form a right angle, the amount of torsion is minimized or eliminated. This optimum position will be—more or less unconsciously—assumed during the process of reading. For wearers of a bifocal correction, the plane of the glasses does not form a right angle with the line of fixation. In the case of a high cylindrical correction, a certain amount of "accommodative" cyclophoria is introduced. This accounts for

* A change in the axis of astigmatism amounting to less than 5 degrees was neglected because it was considered to be within limits of error.

the large number of individuals with astigmatic eyes that are unable to wear bifocal glasses comfortably for near work and have to be provided with two pairs of glasses.

The number of patients with actual cyclophoria is small. They are the ones that need special consideration if at the same time they need astigmatic correction. Routine refraction is performed monocularly and, during the act of fusion, discrepancy between the axis of astigmatism and that of the correcting lens results. Most ophthalmologists perform tests for muscle balance routinely with every refraction. It is suggested to include a test for cyclophoria in all cases of high astigmatism. Should there be such an anomaly present, the determination of the axes of astigmatism binocularly can be performed without elaborate equipment by means of polaroid filters and in minimum time. This small extra effort on the part of the refractionist may cut down materially the number of patients that complain of tilting or distortion after they get their glasses.

TREATMENT OF DELAYED POSTOPERATIVE FORMATION OF THE ANTERIOR CHAMBER*

VICTOR A. BYRNES, M.D.
Randolph Field, Texas

Delayed formation of the anterior chamber following cataract surgery is by no means a rare complication. There is, however, a surprising lack of information regarding it in the medical literature. This article was prepared in an attempt to organize some of the available information on the subject and to present methods of treatment of the condition, one of which is original with the author. This original procedure has only been used in two cases, but was so effective that it is reported in the hope that it will be tried by others so that final evaluation can be made.

SURVEY OF LITERATURE

Textbooks on eye surgery are of little assistance in the care of the patient with delayed formation of the anterior chamber. Berens[1] and Wiener and Alvis[2] do not mention the condition. Stallard[3] mentions it but does not discuss its treatment. Spaeth[4] states that delayed closure of the wound and nonformation of the anterior chamber are rather commonly seen, but he gives the impression that it is a complication of rather minor importance and provides no statistics as to its incidence.

Bracken[5] found, in a series of intracapsular extractions using corneoscleral sutures, that only 0.28 percent showed shallowness or absence of the anterior chamber at the first dressing the morning after operation. This figure may be a bit misleading because the patient may have a reformed anterior chamber at the first dressing and lose it later.

McCool and Dickey,[6] in reporting the results of 100 cases of intracapsular cataract extractions, reported four cases (4 percent) having delayed wound union of over one week's duration.

Kronfeld and Grossman[7] made a study of 120 unselected cataract extractions and found that in 20 instances (16.7 percent) there was a delay of more than three days in the formation of the anterior chamber and in 11 instances (9.2 percent) there was a delay of more than five days.

Castroviejo[8] stated that in a series of 150 cataract operations, using corneoscleral sutures, only two cases of late restoration of the anterior chamber occurred. Townes[9] in his review of 500 cases of cataract extraction, reports one case of delayed wound healing of eight days' duration, but states his records are incomplete in so far as delayed formation of the anterior chamber is concerned.

Due to a peculiar series of circumstances, which will be detailed below, there were five cases of delayed formation of the anterior chamber in a series of 60 cataract operations (8.33 percent) performed between January and June, 1947.

SEQUELAE OF DELAYED FORMATION

Management of the condition is important because of the unfavorable effects of the absence of the anterior chamber with its threat to future vision. The most important complications are iritis, iridocyclitis, secondary glaucoma, epithelial cyst of the anterior chamber, and choroidal detachment. Infection entering through the opening in the wound may also occur.

In discussing Heath's[10] paper, Dunnington[11] states that the usual course of events when the anterior chamber fails to reform is:

1. Hypotony
2. Detachment of choroid and retina
3. Corneal opacification
4. Secondary glaucoma

* Presented before the III Pan-American Congress of Ophthalmology, Havana, Cuba, January 6, 1948.

Iridocyclitis

No figures are available on the incidence of iridocyclitis due to delayed formation of the anterior chamber alone. The relationship of iridocyclitis to postoperative glaucoma and of delayed formation of the anterior chamber to postoperative glaucoma make the following figures of interest.

In Townes's[9] series of 500 cataract operations there was an incidence of iridocyclitis of 5 percent following intracapsular cataract extraction and 10.7 percent following extracapsular extraction.

Hughes and Owens[12] in an analysis of 2,086 cataract operations found a similar decrease in iridocyclitis with the intracapsular operation and stated that iridocyclitis is the main factor in the production of secondary glaucoma. Klein[13] in his analysis of 650 operations showed a similar relationship between extracapsular extraction, iridocyclitis, and secondary glaucoma. The incidence of secondary glaucoma following intracapsular extraction in his series was 0.45 percent and following extracapsular extraction, 2.5 percent.

These authors all stress the relationship between iridocyclitis and postoperative glaucoma. However, Kronfeld and Grossman[7] studied a series in which iridocyclitis was not the cause of the glaucoma. In these selected cases the inflammatory postoperative reaction was slight and had either completely subsided or was definitely diminishing in intensity within 14 days after operation. They have shown that the glaucoma which developed was due to the formation of peripheral anterior synechias and that the extent of these synechias was proportional to the length of time the anterior chamber had been flat. Delay in formation of the anterior chamber of over five days resulted in more extensive and denser synechias than those in which the chamber was flat less than five days. If less than five days, the eye was usually able to compensate for the less extensive synechias and maintain normal tension.

Kronfeld and Haas,[14] in a further study confirmed the previous findings that glaucoma was due to the formation of the peripheral synechias caused by contact between the iris and cornea during the period in which the anterior chamber was flat.

Post[15] reported 20 cases of glaucoma following cataract extraction in which 11 cases (55 percent) had shown delayed formation of the anterior chamber for longer than three days.

On the basis of these studies it would appear that anterior chambers which are flat longer than five days are particularly liable to be followed by persistent secondary glaucoma.

Epithelial cyst

Epithelial cyst of the anterior chamber is a serious condition usually leading to loss of the eye regardless of radiation or other therapy used.

Theobald[16] has shown that epithelial downgrowth occurs through poorly healed wounds. In 9 of 14 eyes enucleated for this reason, there was a poorly healed wound. In 5 of these cases the epithelium could be readily traced into the anterior chamber. She reported that 9 of the enucleations resulted from a series of 8,062 cataracts, an incidence of 0.11 percent. There were several eyes in this same series with epithelial cyst of the anterior chamber which were treated by radiation and not enucleated. These were not included in her statistical study.

Townes[9] reports one case of epithelial cyst of the anterior chamber in 500 operations (0.2 percent). Inasmuch as epithelial cyst of the anterior chamber follows poorly healed wounds, delayed formation of the anterior chamber obviously favors its development.

Choroidal detachment

Choroidal detachment is frequently associated with delayed formation of the anterior chamber and was very severe in one of the cases here reported. Spaeth[4] mentions this troublesome complication. As stated by

Heath[10] and Dunnington,[11] it is probable that it is a result of the hypotony produced by the leaking wound, rather than the cause of the flat anterior chamber as has been stated in some of the older literature.

No figures could be found showing the incidence of infection due to delayed formation, but the increased danger with an opening leading into the anterior chamber is obvious.

Causes of delayed formation

Causes of delayed formation of the anterior chamber may be considered under two headings:

1. Decreased production of aqueous by the ciliary body. This was not a factor in any of the cases in this small series. It is believed that, even though an opening cannot be demonstrated in the classical test, practically all cases of delayed formation of the anterior chamber have a leaking wound.

2. Delay in healing of the corneal wound. This may be due to:
   a. Inaccurate apposition of the wound edges when the wound is closed. (Improperly placed sutures may be a factor.)
   b. Interposition of tissue between the margins of the wound—iris tissue, vitreous, lens capsule, and so forth.
   c. External pressure on the eyeball forcing aqueous out through the partially healed wound. This may be due to eyelid spasm, digital pressure, dressings which press on the eye, and straining or coughing.
   d. Decreased tendency of the cornea to heal due to nutritional disturbances.

Causes of delayed formation in this series

1. External pressure:
   a. One case due to premature removal of a corneoscleral suture resulting in slight opening of the wound.
   b. One case due to digital expression of aqueous from the anterior chamber by the patient rubbing his eye with fingers introduced under his dressing.
   c. One case due to a paroxysm of coughing in a case of chronic bronchitis when prophylactic codeine administration was inadvertently omitted.
2. Decreased tendency of the cornea to heal:
   a. One case of impaired corneal nutrition.
3. Undetermined cause:
   a. One case with formation of conjunctival filtering bleb and almost complete choroidal detachment.

Prophylaxis

It has been pointed out that failure of the anterior chamber to reform was due to external causes in three of the above cases. These were premature removal of a corneoscleral suture, rubbing of the eye with a finger, and a paroxysm of coughing. These are preventable causes and obviously every effort must be made to prevent the occurrence of these and similar incidents.

Alvis[17] and Klein[13] have stressed that for rapid and undisturbed healing of the wound, the lips of the incision should be as smooth and close together as possible and that great care should be taken to free the wound of all debris of capsule, iris, cortex, and clots.

In this connection Chandler,[18] Bracken,[5] Hughes and Owens,[12] and Klein[13] have all stressed the reduction in frequency of delayed formation when adequate corneoscleral sutures have been used.

Prevention of this complication is much more effective than its cure and the importance of well-performed operations and good postoperative care of cataract patients should continue to be emphasized.

Symptoms and Diagnoses

All cases in this series complained of some discomfort in the eye and especially of "watering." There was a subjective decrease in visual acuity noticed by the patients if they had had the anterior chamber formed postoperatively and then lost it.

The classical test consists in placing a

drop of fluorescein in the eye with the patient reclining. Very gentle pressure is applied to the cornea with a strabismus hook. If a leak is present, it will be demonstrated by a washing away of the fluorescein solution from the leaking area.

Dunnington[11] states that this procedure will demonstrate a leak in most instances. Chandler,[18] on the other hand, has found that a leaking area cannot be demonstrated in the majority of cases. In this series, the slitlamp, showing the iris against the cornea throughout most of its area, was the best diagnostic aid and the one most useful in formulating the operative procedure to be used.

Technique of the original cataract operation

The original cataract extractions were done by two operators using the same technique. The routine consisted of the usual van Lint akinesia, retrobulbar anesthesia, and subconjunctival blebs of cocaine and adrenalin.

The conjunctiva was incised from the 3- to 9-o'clock positions with a Graefe knife and elevated with Stevens scissors to form a Kuhnt flap. Incisions were made half way through the cornea at the limbus at the 1:30- and 10:30-o'clock positions and two corneoscleral sutures (6-0 black silk) were put in place, looped, and left untied.

The anterior chamber was entered with a Graefe knife and the incision enlarged to include almost the upper one-half of the cornea at the limbus. Iris forceps were inserted and a peripheral iridotomy made with a de Wecker scissors.

In two of the cases the incision was extended through the pupillary sphincter to form a keyhole pupil. In the other three cases the cataract was extracted through a round pupil. The lens was extracted intracapsularly in four cases with the Arruga forceps using a strabismus hook below for counter pressure. In the other case an intentional extracapsular extraction of a traumatic cataract was done.

After removal of the lens, the anterior chamber was irrigated and the iris reposited. Corneoscleral sutures were tied and air was injected into the anterior chamber. The Kuhnt flap was pulled down over the corneal wound and sutured, using two 6-0 black silk sutures.

TABLE 1

Length of time until the anterior chamber was lost: until surgical correction: and until formation of the chamber

Case No.	Original Operation Until Anterior Chamber Was Lost	Anterior Chamber Flat Until Corrected	Anterior Chamber Formed After Surgical Procedure
1	3 days	8 days	next day
2	3 days	9 days	next day
3	6 days	10 days	next day
4	11 days	11 days	next day
5	0 days	12 days	next day
		6 days	next day
		14 days	next day

Eserine and penicillin ointment were instilled and the eyelids splinted with a thin sheet of wet cotton. Eye dressings and a double protective eye mask were applied. The patient was then placed in a crib bed. He was required to remain flat on his back for four hours, after which he was permitted to turn on the unoperated side. He was not permitted out of bed until the eye had been dressed on the second postoperative day.

Careful perusal of the operative techniques did not reveal any demonstrable cause for the delayed formation of the anterior chamber in these cases.

Treatment

No article on treatment of this condition could be found in the literature. In discussing MacMillan's[19] paper, McLean[20] first mentioned using air injection for the treatment of delayed formation of the anterior chamber and it is now being used by a number of other prominent ophthalmologists, including Chandler[18] and Guyton.[21]

Chandler tests the wound for leakage and, if found, cauterizes it with trichloracetic acid or actual cautery. If no leak is found and the chamber has not formed by the seventh postoperative day, air is injected into the anterior chamber.

A small knife is used to make a slanting incision in the lower cornea away from the original cataract incision. It should be 3 to 4 mm. from the point of engagement on the surface of the cornea to the entrance into the anterior chamber over the iris.

A small hypodermic needle on a syringe can be put part way into the tract of the incision but not into the anterior chamber. With the needle in the tract, sharp pressure on the plunger of the syringe will force air into the anterior chamber. The slanting incision acts as a trap door and retains all the air which enters. If the needle is placed all the way into the anterior chamber, much of the bubble will escape alongside the needle.

The air injection restores the anterior chamber and separates the iris from the cornea at the angle. When the air is absorbed, it is usually replaced by aqueous and the chamber remains formed. Inasmuch as all the cases reported in this series had leaking wounds, this method was not used. No statistics on its efficacy could be located.

In those cases in which a leak can be demonstrated in the anterior chamber, Dunnington[11] feels that, as a rule, chemical cauterization is insufficient. He, therefore, places a suture through the leaking area and covers it with a conjunctival flap.

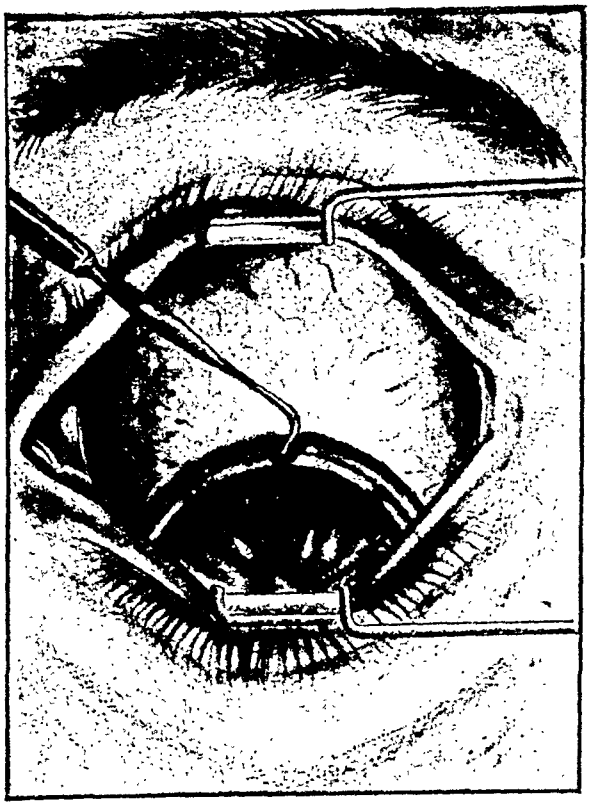

Fig. 1 (Byrnes). In leaking wounds where separation of the surface is minimal, cauterization with a heated strabismus hook will usually produce adequate closure. The conjunctival flap is resutured over the wound.

Surgical procedure followed in this series

This varied somewhat with the case. In all cases the Kuhnt flap was reëlevated. No difficulty was experienced in doing so and in no case was there any resistance or increased friability of the tissues. The wound was exposed throughout its length and in each case inspection alone was all that was required to identify the leaking area.

In three cases the procedure used was to heat a strabismus hook in the flame of an alcohol lamp and lightly cauterize the leaking area of the wound to seal it and stimulate healing. The flap was then replaced in these three cases and sutured in position over the wound. In three cases, the anterior chamber had formed by the following morning and the postoperative course was entirely uneventful.

In Case 4 there was a slightly larger opening in the cornea. The lips of the wound were separated 0.5 mm. for a distance of approximately 1.5 mm. where the corneoscleral suture had been removed at the 10:30-o'clock position on the cornea. It was closed with a single silk suture.

It was felt that a simple cauterization

Fig. 2 (Byrnes). When separation of the lips of the wound has been more extensive or there is a decreased tendency of the cornea to heal, very shallow electrodiathermy punctures along the wound margins and extending beyond both extremities are effective.

would be ineffective. For this reason the 0.5-mm. electrodiathermy needle, ordinarily used for retinal detachment operations, was used. With it, tiny, very shallow punctures were made in the cornea and sclera 1 mm. from the wound edges and extending 0.5 mm. beyond either end.

Thrombin was applied to the wound and the cauterized area and to the under surface of the conjunctival flap. The flap was then reapplied to the wound surface and sutured in position. The anterior chamber was formed the next morning and remained so. It had been flat for the previous 11 days.

Case 5 was one in which it is believed the procedure may be credited with saving an eye. This 84-year-old woman had a nutritional disturbance of her cornea and her anterior chamber failed to form after operation. After waiting 12 days, her corneal wound was exposed and an opening found from the 12- to 2-o'clock positions. The corneoscleral suture had cut through the corneal substance which was grayish in color and soft in consistency.

Two corneoscleral sutures were put in place, and the wound was lightly cauterized with a hot strabismus hook. The original suture at the 10:30-o'clock position was still holding. The conjunctival flap was replaced. On the following morning she had an anterior chamber, which she lost by the next day.

She was reoperated at the end of six days. The suture placed at the original operation at the 10:30-o'clock position had cut through, as had one of the sutures placed at the second operation. The wound was resutured with two 6-0 silk sutures and again cauterized and the conjunctival flap pulled down. Again she had an anterior chamber the following morning which she lost in two days.

Ten days later, she had her final operation in which shallow, tiny electrodiathermy punctures were made in the cornea and sclera, thrombin applied, and the conjunctiva pulled down and resutured. Her anterior chamber was formed the next day and has remained so since.

This eye obviously had a decreased tendency to heal and would probably have been lost if it had not been possible to restore wound continuity and improve corneal nutrition. Waiting periods of 12, 6, and 14 days between operations should have been adequate to allow spontaneous healing to occur.

The use of thrombin under the conjunctival flap was prompted by the experience of Tidrick and Warner[22] in the use of hemostatic agents for the attachment of skin grafts. Perhaps the application of thrombin

to the incision area and fibrinogen to the under side of the conjunctival flap would have been effective in the formation of a firm coagulum and it is planned to use this procedure if another occasion arises. The firm fibrin clot so formed should be effective in sealing the anterior chamber.

Postoperative course

The reaction to operation was in all cases slight and, as a rule, the eyes looked better one day postoperatively than they had immediately prior to operation.

The patients stated their eyes felt much better and they were grateful for the decreased "watering." They also noted improved visual acuity which made them feel more optimistic about their future vision.

It is believed that the improved patient comfort and his earlier recovery alone would compensate for the additional surgical procedure, even without the possible improvement in final visual results and the decreased danger of complications.

Recommended procedure

On the basis of the data presented above it is believed that no anterior chamber should be allowed to remain flat more than five days postoperatively. It is considered that the following is the method of choice in treatment.

1. In cases in which no leak can be demonstrated in the anterior chamber, air should be injected through a slanting incision in the lower cornea as mentioned above.

2. In cases with a demonstrable leak in the wound or when air injection has been ineffective:

   a. Elevation of the conjunctival flap.

   b. Use of electrodiathermy to cauterize the edges of the leaking wound lightly, if these edges are in close approximation. In wider wounds or those in which the cornea has shown decreased tendency to heal because of nutritional disturbances, corneoscleral sutures should be inserted, and the application of very shallow punctures, 1 mm. from the wound edge and about 2 mm. apart, extending beyond the ends of the wound opening is indicated.

   c. Application of thrombin and perhaps fibrinogen to the wound area.

   d. Suture of the conjunctival flap over the wound.

   e. Application of the eye dressing.

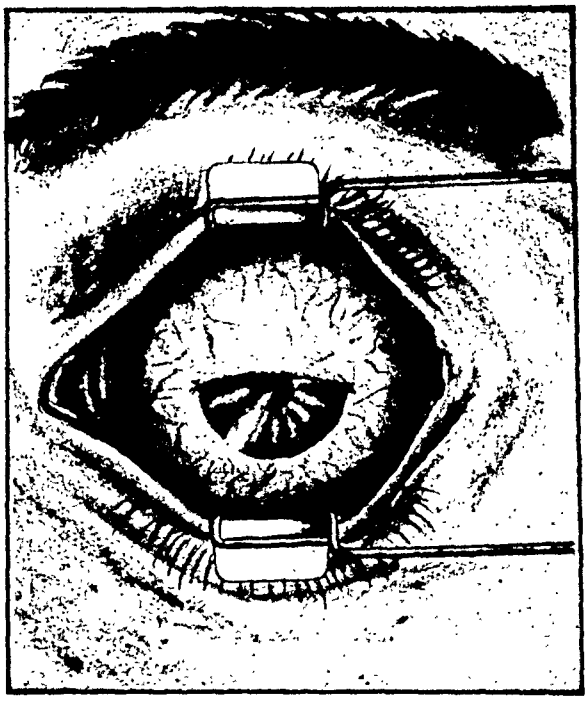

Fig. 3 (Byrnes). The conjunctival flap is resutured over the corneal wound following repair of the leaking area.

Case reports

The following cases are reported in abstract form in an attempt to present only the data which are pertinent to the present discussion. In all cases, laboratory work, unless otherwise mentioned, was negative. Complete eye examinations were done on each patient, but only positive findings are listed.

Case 1.

D. B., a white man aged 63 years.

February 9, 1947. Admitted to the Eye Service from General Surgery for cataract operation O.D. He had a chronic bronchitis with cough which had been improved as much as possible by medical management. He was given codeine (0.032 gm. every 4 hours) to control cough.

February 10, 1947. Combined intracapsular cataract extraction through a round pupil.

February 12, 1947. Eye dressed. Anterior chamber formed.

February 13, 1947. Anterior chamber flat. Patient had a paroxysm of coughing last night when codeine was inadvertently omitted. The patient also admits having inserted a finger under his protective shield to rub his operated eye.

February 17, 1947. Anterior chamber still flat. Choroidal detachment slightly increased. No iris prolapse.

February 21, 1947. Taken to operating room. Kuhnt conjunctival flap reëlevated. There was a small leaking area at the temporal end of the wound. A strabismus hook was heated in the flame of an alcohol lamp and the leaking portion of the wound cauterized lightly. The conjunctival flap was then resutured in position.

February 22, 1947. Anterior chamber reformed. The eye condition good.

March 31, 1947. Eye quiescent. Patient refracted. He has a large central area of chorioretinitis adjacent to the macula. Vision: O.D., 6/12.

This patient's failure to form his anterior chamber was apparently due to a paroxysm of coughing or pressure of his finger under his dressing, or both.

CASE 2.

R. E. S. was a white man aged 82 years.

November 7, 1946. Presented at Eye Clinic complaining of poor vision. Examination showed infiltration of the left cornea with considerable vascularization and slight left exotropia. Some slight corneal infiltration O.D. also. Kahn and Wassermann tests negative. He was given dionin and capsules of riboflavin (3 mg.), ascorbic acid (50 mg.), and nicotinic acid (5 mg.) twice daily.

December 17, 1946. Cornea O.D. now clear. Subjective improvement in vision.

December 31, 1946. Vision 10/200. Eyes quiescent. Lacrimal-sac irrigation and culture negative.

March 3, 1947. Arteriosclerotic vessels and mild central macular degeneration visible. Not well seen because of lens opacity. Admitted to hospital for operation.

March 4, 1947. Operation delayed because of cough and slight fever.

March 21, 1947. Recovered from upper respiratory infection. Intracapsular cataract extraction O.D. through round pupil.

March 23, 1947. Eye dressed, anterior chamber formed; condition good.

March 24, 1947. Choroidal detachment in superior and inferior temporal quadrants. Anterior chamber very shallow.

March 28, 1947. Choroid markedly detached. Tension 3 mm. Hg (Schiøtz); anterior chamber very shallow.

April 1, 1947. Eye still soft with choroid almost completely detached. The conjunctiva appears to be very slightly elevated at the 12-o'clock position; somewhat like the filtering cicatrix seen after a trephining operation. Patient taken to the operating room and the Kuhnt conjunctival flap reëlevated. There was a small leaking area near the 12-o'clock position on the cornea with the lips of the wound in good approximation. There was no prolapse of any kind. The leaking area was cauterized lightly with a heated strabismus hook and the conjunctival flap resutured over the wound.

April 2, 1947. Eye dressed. Anterior chamber formed; condition good.

April 8, 1947. Much improved. Anterior chamber of normal depth. The choroid almost completely reattached.

July 7, 1947. Fundus clear and readily seen. Choroid reattached entirely; eye quiet. Refracted vision 6/12, with macular degeneration present.

This patient apparently had a filtering cicatrix under his conjunctival flap producing the hypotony which he showed. This in turn was probably responsible for the almost daily increase in the extent of his choroidal detachment. The choroid did not reattach until the opening in his anterior chamber was sealed and intraocular pressure was returned to a normal level.

CASE 3

H. V. was a white man, aged 45 years.

March 29, 1947. While hammering on a metal bedstead this patient was struck in the right eye by a fragment. Examination showed a piece of steel (3 by 1.5 by 0.25 mm.) buried deep in the cornea and projecting into the anterior chamber. The lens capsule had been opened by the fragment. The foreign body was removed by electromagnet through the wound of entry. The anterior chamber was irrigated with penicillin solution (1,000 units per cc.), and he was given penicillin parenterally (30,000 units every 3 hours).

April 1, 1947. Eye slightly reddened. No obvious infection; lens has started to swell. No pain. Intraocular pressure 10 to 12 mm. Hg (Schiøtz).

April 4, 1947. Developed pain in the right eye. Tension 35 mm. Hg (Schiøtz). Extracapsular cataract extraction using full cataract incision. This was necessitated by the firm lens material. Incision, sutures, and closure were as described for the other operations.

April 6, 1947. Anterior chamber has reformed.

April 10, 1947. Anterior chamber shallow. Patient states he managed to work his finger under his protective dressing and rub his eye.

April 15, 1947. Iridocyclitis O.D. mild. Keratic precipitates and a 2+ flare present. Iris markings obscured. Started on atropine, salicylates, heat, and foreign-protein therapy. Anterior chamber still flat.

April 18, 1947. Anterior chamber still flat. Operated. The conjunctival flap was reëlevated. There was a leaking area at about the 1-o'clock position. The lips of the wound were cauterized lightly with a heated strabismus hook and the conjunctival flap resutured.

April 19, 1947. Anterior chamber formed. The

eye appears less irritated. Treatment of iridocyclitis continued.

April 21, 1947. Has corneal bedewing, plus-minus flare, no cells, iris markings slightly obscured. He has a pupillary membrane which is chiefly due to the iritis. Discharged to out-patient status to return in three days.

May 6, 1947. Patient finally returned for out-patient observation of his iritis. He has not been using the treatment ordered. Started on iridocyclitis treatment again.

June 17, 1947. The eye is quiescent; not painful or tender; pupillary membrane not touched because of possibility of exacerbation of iridocyclitis. No refraction done.

This patient was one with a traumatic eye with foreign body. His anterior chamber was flat five days before he had a manifest iridocyclitis. Whether earlier repair of his leaking wound would have prevented the onset of the condition is unknown. Certainly the mild surgical interference did not aggravate the iridocyclitis and was apparently beneficial. It was effective in restoring the anterior chamber.

CASE 4

A. P. was a white woman, aged 83 years.

March 18, 1947. Admitted to hospital with severe burns of hands.

April 14, 1947. Transferred to the Eye Service for cataract extraction. Fundus not visualized because of cataract, 2-point discrimination poor.

April 18, 1947. Operation postponed because of fever, cough, and diagnosis of mild pneumonia. Given penicillin by the Medical Service.

April 25, 1947. Cleared by Medical Service for operation. Intracapsular cataract done through a round pupil.

May 5, 1947. Patient, in order to leave the hospital, desired early removal of corneoscleral sutures. One suture carefully removed. Anterior chamber slowly flattened out immediately thereafter.

May 10, 1947. Still has flat anterior chamber. Slitlamp shows only a small central area where cornea and iris are not in apposition.

May 16, 1947. Condition unchanged; taken to the operating room; conjunctival Kuhnt flap reëlevated. There was a leaking area at the 10:30-o'clock position on the cornea where the conjunctival suture had been removed. The wound edges were superficially cauterized, using a 0.5-mm. electrodiathermy needle, and small, very superficial electrodiathermy punctures were placed 1 mm. from the wound margin in cornea and in sclera. These were about 2-mm. apart and extended beyond both ends of the leaking portion of the wound. Thrombin was applied to the wound and cauterized areas and the conjunctival flap was sutured in position over the wound.

May 17, 1947. The anterior chamber has formed.

June 18, 1947. The eye is quiescent. Normal anterior chamber and tension. The media are clear and the fundus readily visualized. There are marked arteriosclerotic degenerative changes present. Vision cannot be corrected to better than 6/120 due to the central lesion.

CASE 5

L. N. was a white woman, aged 84 years.

April 10, 1947. Admitted to the Eye Service because of defective vision. Except for cataracts, her examination was essentially negative. Tension was 19 to 20 mm. Hg (Schiøtz).

April 11, 1947. Combined intracapsular cataract extraction.

April 13, 1947. Eye dressed; anterior chamber shallow, but appears to be formed.

April 16, 1947. Anterior chamber very shallow.

April 23, 1947. There is a mild obscuration of the iris markings and a thin pupillary membrane has formed. Anterior chamber flat. Taken to operating room where the conjunctival flap was reëlevated. There was an opening from the 12- to 2-o'clock position in the cornea where the corneoscleral suture had cut through the corneal substance. The corneal substance was grayish in color, somewhat opaque and soft in consistency. An iris repositor could be readily passed into the wound. Two additional 6-0 silk sutures were put in place and the wound edges lightly cauterized with a heated strabismus hook. The conjunctival flap was replaced.

April 24, 1947. Anterior chamber is formed, but still not as deep as normal.

April 25, 1947. The anterior chamber is flat again. Patient complains of her eye watering.

April 30, 1947. Patient reoperated. Technique used at previous operation was used again. The suture at the 10:30-o'clock position has now cut through the soft corneal substance as has one of the sutures placed at last operation at the 12:30-o'clock position. Resutured with two more 6-0 black silk sutures and again cauterized with a heated strabismus hook and the conjunctival flap replaced. The corneal tissue is still friable and gray in color.

May 1, 1947. Anterior chamber formed. The eye is improved.

May 2, 1947. Anterior chamber shallow.

May 3, 1947. The anterior chamber is flat and patient again complaining of "watering" of her eye.

May 12, 1947. Patient had a cardiac episode; possibly a myocardial infarction. Treatment prescribed by the Medical Service.

May 16, 1947. Patient still has a flat anterior chamber. Taken to operating room and an opening found from the 10- to 12-o'clock position in the cornea. The cornea is still gray, soft, and friable. The same operative procedure, using electrocautery and thrombin, used in Case 4 was used here.

May 17, 1947. The anterior chamber is now formed, but still shallow.

May 22, 1947. Anterior chamber is getting deeper. The eye looks better.

June 3, 1947. Ready for discharge from the hospital. Anterior chamber present. She is not yet ready

for refraction, but her cornea is clearing. After July 1, 1947, she had several attacks of glaucoma with tension, O.D., up to 45 mm. Hg (Schiøtz). This has now recovered.

This case of impaired corneal nutrition is one in which the eye would in all probability have been lost without the surgical procedures employed. If the last operation had been done first, it is quite likely this patient would have had less pupillary exudate formed and might well have escaped the temporary secondary glaucoma which followed the prolonged period of 36 days' duration in which her anterior chamber was flat most of the time.

Summary and Conclusions

1. Absence of the anterior chamber following cataract operation is considered dangerous to the future welfare of an eye because of the possibility of iritis, iridocyclitis, secondary glaucoma, epithelial cyst of the anterior chamber, choroidal detachment, and infection.

2. No anterior chamber should be allowed to remain flat more than five days postoperatively.

3. Surgical procedures have been reviewed which are believed to be effective in the treatment of the condition.

4. An original procedure has been described for use when there is reason to believe there may be a decreased tendency of the wound to heal. It is hoped that others will report their experiences with this method.

THE USE OF IMMUNE GLOBULIN IN THE TREATMENT OF UVEITIS*

BERNARD KRONENBERG, M.D.
New York

The treatment of uveitis frequently presents a difficult problem. This disease usually is treated by injection of foreign proteins, by local therapy, and by eradication of any foci of infection. In many cases these procedures do not arrest the condition. A new approach in the treatment of uveitis is the use of the immune globulin.

Immune serum globulin, whether prepared from human plasma or placentas, contains gamma globulin as the active principle. While McKhann and Chu[1] enlarged our concepts concerning the heterogenicity of plasma, researches secondary to the war effort added a great impetus to a more precise understanding of the functions of the various components of human plasma. By electrophoretic means, the heterogeneous nature of plasma could be suspected. The studies of Cohn and his associates[2] made possible the fractionation of plasma, thereby permitting a more accurate study of its various components.

Gamma globulins comprise about 11 percent of the plasma proteins and are found primarily in Fraction II, to a much smaller extent in Fraction III. This component of plasma is thought to have a molecular weight of 156,000 in contrast to 69,000, the weight assigned to serum albumin.

CLINICAL INTEREST

Clinical interest in gamma globulin lies not in its physical constants but in the fact that many of the antibodies elaborated by the defense mechanisms of the body are concentrated in this fraction. Some of these antibodies are those corresponding to the following antigens: typhoid O, typhoid H, influenza A, mumps, diphtheria toxin, and streptococcus toxin. Undoubtedly many others are present which do not lend themselves so easily to identification by biologic methods. In fact, it might appear that the limitations of gamma globulin are determined by the degree of refinement and the multivalence of the plasma pool from which it is derived.

Two epidemic diseases, measles and infectious jaundice, have lent themselves nicely to the exposition of the efficacy of gamma globulin in the treatment and prevention of these diseases. Ordman, Jennings, and Janeway[3] studied the application of this agent to epidemic measles. They showed not only that gamma globulin may be administered without reactions but that it prevented or attenuated the disease in contacts, depending on the size of the inoculum and the duration after exposure when the globulin was administered. Subsequently other reports have justified the confidence in gamma globulin as a therapeutic agent in the treatment and/or prophylaxis of measles.

Stokes and Neefe[4] subsequently applied this principle to the prevention of infectious hepatitis in a children's camp where this disease was prevalent. The figures are more difficult to evaluate because of the greater variability in incubation period, susceptibility, and so forth. With these well-confirmed, practical demonstrations of the usefulness of gamma globulin, it became apparent that clinical exploration in many other diseases might be fruitful. Consequently the present study was undertaken.

TREATMENT OF UVEITIS

The theory upon which I instituted the injections of immune globulin is based upon the fact that the organism requires antibodies to combat infection. In the treatment of uveitis, the function of foreign proteins

* Read before the New York Society for Clinical Ophthalmology, May 5, 1947.

is to stimulate the production of antibodies within the organism itself. It seemed logical to me, therefore, that the patient would obtain greater help in combating the infection if antibodies were supplied directly by injections. For this reason, I used injections of concentrated immune globulin containing both bacterial and virus antibodies.

Results

Encouraging results have been obtained in the treatment of various forms of uveitis by injections of massive doses of immune globulin in conjunction with the use of foreign protein.

Six cases of acute uveitis were treated in this manner, with good results. A detailed report of three of these cases will indicate the method of treatment.

Case reports

Case 1. Mr. W. S., aged 34 years, consulted me first on March 24, 1947. He gave a history of acute inflammation of the right eye of 3 weeks' duration, and of the left eye of 3 days' duration. Diagnosis of acute iridocyclitis of both eyes was made. He had been treated elsewhere with foreign protein, with no result. The patient gave a history of having had an active lung lesion of tuberculous nature in 1935, for which he was treated successfully with a therapeutic pneumothorax in 1941.

This patient was treated by me with triple typhoid injections intramuscularly followed by intramuscular injections of immune globulin for 4 to 5 days. He was then given typhoid vaccine and again treated with immune globulin. This treatment was given for 4 to 5 days; in all, 4 courses of treatment were given.

At his first visit his vision was: R.E., 20/400, L.E., 20/200. By April 29, 1947, his vision had returned to: R.E., 20/25; L.E., 20/30. On reëxamination on August 15, 1947, his vision had returned to 20/20, O.U., and there was no evidence of any ocular lesion.

The severity of this iridocyclitis and its response to this method of therapy leads me to believe that immune globulin played a large role in his successful recovery.

Case 2. Mr. T. H., aged 57 years, was first seen in April, 1945, with an acute iridocyclitis of the right eye. He had recurrent attacks every 3 or 4 months which were treated each time with foreign protein. His last attack in April, 1947, was treated with typhoid vaccine and immune globulin. His vision returned to normal, and 10 months later there had been no further recurrence.

Case 3. Mrs. M. B., aged 51 years, consulted me on August 24, 1947, with a history of a scratch on the left eye with a stick 6 weeks before, which had developed into a corneal ulcer. She was treated at an eye institute for five weeks with sulfa drugs, penicillin, streptomycin, and foreign-protein therapy. A paracentesis was also performed. Examination revealed evidence of old trachoma of both eyes.

The left eye was markedly congested, and there was a dense, white infiltrate situated in the central part of the cornea, involving the stroma. This area did not stain with fluorescein. The cornea was vascularized, and a hypopyon was present in the lower third of the anterior chamber. The iris was bound down. Vision was light perception only.

The patient received 1 cc. of typhoid subcutaneously followed by 3 doses of 5 cc. of immune globulin. On September 19, 1947, the corneal infiltrate desquamated as a sharply defined disc, with healed corneal epithelium underneath. The hypopyon had completely disappeared. At the present time, the eye is completely white. Vision is fingers at two feet, and the patient is comfortable. In all, the patient received a total of 3 courses of injections.

Conclusion

A preliminary report on the use of immune globulin in acute forms of uveitis has been presented. Immune globulin seems to have helped in clearing up a number of

severe cases of uveitis, which did not respond to the usual therapy. Immune globulin should be used in conjunction with foreign proteins and other local therapy. The work is being continued on the use of immune globulin in the treatment of acute and chronic uveitis. Further reports on the results of this work will be made.

737 Park Avenue (21).

ON NEW TYPES OF OCULAR DISEASES*

ADALBERT FUCHS, M.D.
New York

Some of the new types of ocular diseases, which I have had the opportunity to describe, cannot be found in the different handbooks; some of them were described later on by another author, sometimes in numerous publications, and became so known; some were accepted by special textbooks and so saved from oblivion.

1. DIVIDED NEVI

In 1919[1] I described a special type of nevi of the lids, interesting because they are divided by the palpebral fissure. I called them *divided nevi*. Either such a nevus occupies the angle of the lids or one half is on the upper lid and the other on the lower lid. These very rare divided nevi are of a special scientific interest; we know that the lids are closed by epithelium during some time in the fetal life, but it is not yet known if the nevi originate from the epidermis or from the cutis. The divided nevi make it very probable that the place of origin is the epidermis as the connection of the lids is made only by epithelium in the fetal life; it is also likely that the anlage of the nevi is developing just in the time of this connection of the lids.

Since my publication I did not see any other such nevus in Europe and I read only once a paper in which such a case was operated upon and the nevus excised. In China, where nevi are exceedingly frequent and often enormous, I saw only one case

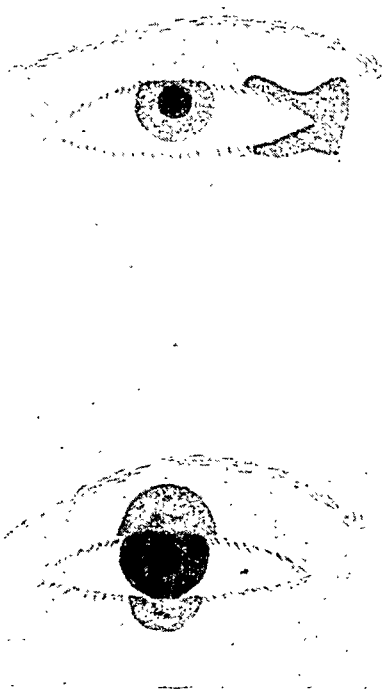

Fig. 1 (Fuchs). Divided nevi. (Above) At the inner angle of the palpebral fissure. (Below) At the middle of the upper and lower lids.

* Presented at the III Pan-American Congress of Ophthalmology, Havana, Cuba, January, 1948.

where the nevus was situated partly on the upper and partly on the lower lid and another case where the inner angle of the palpebral fissure was occupied by the nevus (fig. 1). A third case which I saw in Nanking had been operated upon but soon the lower part of the nevus, which had originally surrounded the inner angle, recurred. This case shows again how dangerous it is to operate on a nevus because, frequently, a number of these cases lead, after an operation, to sarcoma. Arcuri pleads for the removal of every nevus.[2]

2. Sjøgren's syndrome

As a special type of disease, I published the case[3] of a woman, aged 54 years, the secretion of whose tear glands and submaxillary and subligual glands had entirely stopped. She was not able to weep, her eyes had a very disagreeable sandy sensation and she had difficulty in eating anything solid like meat or bread, which she had to wash down with soup or water. The very annoying dryness of the conjunctiva was later on called conjunctivitis sicca by Sjøgren[4] and the syndrome was called later on Sjøgren's syndrome.

A real cause of this condition was not found. It may be that a hormonal disturbance or, as it seems more likely to me, a disturbance of the center of secretion in the mesencephalon is the origin.

3. Behçet's syndrome

The following interesting case was emphasized as a special new disease.[5] A Turkish dentist had frequent attacks of iridocyclitis with hypopyon for years, accompanied by very painful infiltrations in the muscles and fascies and also ulcers in the mouth and on the scrotum. He was examined very carefully but no etiologic factors could be detected. One infiltration of a muscle was excised and the biopsy showed numerous polynuclear leukocytes but no germs or parasites. This man had many posterior synechias and a membrane in each pupil and had become nearly blind. He was treated with salvarsan and showed some improvement.

I tried to get information about this very striking clinical syndrome by asking doctors who had worked as prisoners of World War I in Asia but nobody had observed such a case. Later on Behçet from Istanbul published a few cases of this disease in different medical journals and since then this disease is called Behçet's disease. Just recently such cases were described by different authors.[6] This disease apparently does not occur in China, at least many eye doctors (about 100) whom I asked about it had not observed such a case, the symptoms of which are so conspicuous.

4. Keratitis parenchymatosa linearis

In 1926 I emphasized a new type of interstitial keratitis due to hereditary syphilis and I gave it the name *keratitis parenchymatosa linearis.*[7] A very slight interstitial keratitis starts as a line which detaches itself from the limbus; this slightly undulated line-shaped opacity migrates slowly across the cornea to the other side. This opaque line shows precipitates on the posterior surface of the cornea and gives a very characteristic clinical picture. The syphilitic etiology was shown in all these cases. This type of disease I believe could be used as an argument against the idea that the interstitial keratitis is an allergic disease as it was maintained by some authors.

In recent years I have seen no more of this very rare type of disease, but it is not astonishing since keratitis parenchymatosa became very rare in Vienna.

5. Neuritis syphilitica papulosa

Another new type of syphilitic disease I called *neuritis syphilitica papulosa.*[8] This most grave papillitis (fig. 2) is characterized by a mass of exudate covering the papilla in such a degree as is not found in any other disease except a beginning case of metastatic ophthalmia. This exudate does

not permit observation of the outlines of the papilla and leads sometimes to a focus on the choroid. Besides there are very severe vitreous opacities and numerous hemorrhages of the retina. The disease occurs in the first two years after the syphilitic infection and needs a long time for recovering, usually it takes a year until the vision gets better and sometimes the vision becomes very good; the visual field may show a sector-shaped defect. As a result of the papillitis frequently a comma-shaped strand of connective tissue starts on the papilla and the point leads to an atrophic choroiditic focus (retinitis proliferans).[9]

Report of a case. A man, 33 years of age, acquired syphilis two years ago and was treated by neosalvarsan, but Wassermann tests were never negative. Two months ago

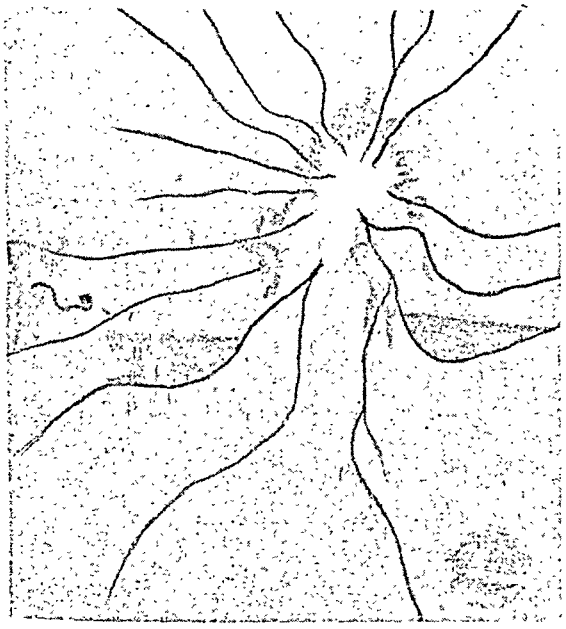

Fig. 2 (Fuchs). Neuritis syphilitica papulosa.

the left eye (fig. 2) showed a very severe impairment of vision and many dust-shaped vitreous opacities. After 1½ years the vision became 6/8. The visual field showed a sector-shaped retraction from above and temporal. The spinal fluid which was highly positive became negative five years after the picture was made.

When I was in Peiping as visiting professor on the P.U.M.C. (1923-24) I saw such a case and used it in my publication. During my stay in China with UNRRA-WHO last year I saw again such a case in

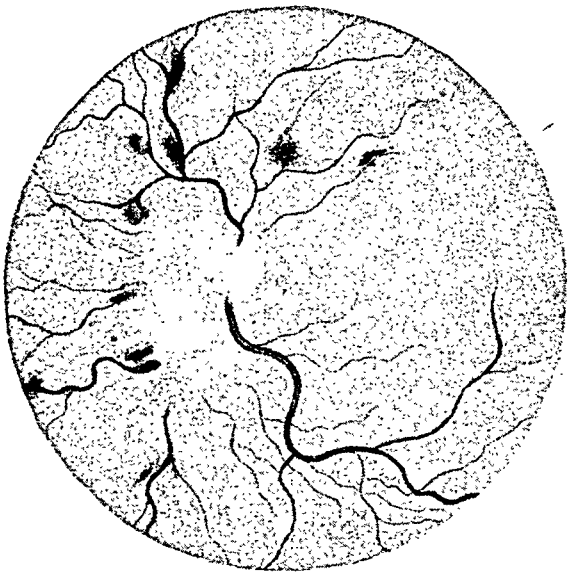

Fig. 3 (Fuchs). *Neuritis syphilitica papulosa.* This drawing is from the collection of Dr. S. K. Chang of Shanghai. The patient, a man, aged 27 years, had had visual disturbances for six weeks. Vision was 0.1. Syphilis had been acquired about 1½ years previously. The Wassermann reaction was a plus three. He was given three salvarsan injections at one-month intervals. After two months, vision was 0.5. The hemorrhages had disappeared.

Chengtu-Szechwan. It was a binocular case which differed from the published cases only by the fact that there were very few vitreous opacities. The young man was seen only once in the E.E.N.T. Hospital and did not return so I was not able to have a picture of his fundus. The vision was very poor and the syphilitic infection had been acquired a few months previously.

I found a typical picture of such a neuritis syphilitica papulosa in the collection of Dr. S. K. Chang in Shanghai which was published as a neurorezidive (fig. 3).[10] Dr. Chang had thought that this papillitis was a Herxheimer reaction and was due to the three salvarsan injections the patient had received some time ago. I do not doubt that

this papillitis has developed independently of it just as all the cases I had seen got the papillitis spontaneously.

These two syphilitic diseases, keratitis parenchymatosa linearis and neuritis syphilitica papulosa were mentioned in the third volume of Duke-Elder's textbook.

6. Myopia inversa

Myopia inversa[11] is not a very rare change of the fundus. One finds a large atrophic zone of the choroid next to the papilla but not on the temporal side as in a common high myopia but on the *nasal* side; that means on the inverse side. This atrophic area can be several disc diameters in size and can also surround the whole papilla, just as in circumpapillary atrophy of the choroid in cases of high myopia, with the exception that the broadest part is lying on the nasal side and the narrowest area on the temporal side. Such a nasal atrophic zone of the choroid can get larger during the years. Sometimes this nasal atrophy is present in both eyes; sometimes it is only in one eye, while in the other eye a temporal atrophic zone is present.

The nasal atrophy differs from the typical congenital white narrow nasal conus; the zones are much bigger and they are quite different in shape; their color is yellowish and not whitish like the nasal conus. A development of such a nasal atrophic zone out from a congenital conus is not likely because I did not see in one of these cases a differentiation of a white congenital scleral nasal conus in the yellowish atrophic zone.

The central vessels in the papilla divide as a rule in an inverse type; the temporal half of the papilla appears as a rule normal and a special supertraction of the temporal border of the papilla is present only in some instances. The fovea centralis sometimes seems to lie nearer to the papilla than normal but also in those cases I found the blindspot on the normal place of the visual field.

The cases of myopia inversa differ from the cases of the common high myopia with temporal atrophic zone in the following point. If there is a temporal atrophic choroidal zone, we are, as a rule, able to estimate the height of the myopia by the breadth of the zone; a broader zone corresponds usually with a higher myopia. This is different in inverse myopia because very often the myopia is much smaller than we would expect, although the nasal atrophic zone is very broad.

The cause of this nasal atrophic zone is without doubt a pulling on the choroid toward the nasal side. We can find sometimes a higher myopia of the nasal part of the fundus than of the posterior pole of the eye or of the temporal side of the fundus. That shows us a special unusual ectasia of the nasal sclera. This ectasia is based on an embryologic anlage that is made clear by the so frequent inverse division of the vessels. But the fact that the nasal fundus shows often a poor pigmentation shows us that we may have here, besides a congenital poor content of pigment in the pigment epithelium, a traction of the choroid, just as we have that often in common high myopia; one can see excellent examples of this condition sometimes in a case of high myopia with staphyloma verum[12] where in front of the dark reflex of the scleral step the fundus is sometimes brownish-red while the area of the staphyloma verum appears albinotic.

To this group of myopia inversa belong also the exceedingly rare cases, where the papilla and its neighborhood are normal in spite of high myopia but where the nasal fundus is markedly poor in pigment and shows considerably higher myopia than the temporal fundus. Such a case, that of a woman, 32 years of age, had a perfect normal papilla; the temporal fundus was reddish-brown and changed suddenly in the vertical meridian to a tesselated nasal fundus.

Her corrected vision was: R.E., −11D., 5/8, on the posterior pole of the eye; but −14D. sph. ⊂ 0.75D. cyl. ax. 25° in adduction; L.E., −6D., 5/8, on the posterior

pole of the eye, but −9D. sph. ⊂ +0.5D. cyl. ax. 180° in adduction.

In China I saw two cases of inverse myopia: the first, that of a man, aged 32 years, had refractive errors of: R.E., −6D. and nearly no conus at all; L.E., the same and an atrophic zone of a 1/2 p.d. breadth on the nasal side.

The second case was a high myopic man, 42 years of age, with a cerebellar tumor. On the right eye a common circumpapillary atrophy of the choroid was present and the disc was indistinct and very little swollen; while on the left eye there was a large nasal atrophy of the choroid and a very marked choked disc (fig. 4).

The second case was especially interesting for the following reasons; I had emphasized in a previous report that, in eyes with circumpapillary atrophy of choroid due to high myopia, frequently other changes of the fundus and the papilla do not develop. So highly myopic eyes often show absolute glaucoma and perfect blindness and a simple atrophy of the optic nerve without glaucomatous excavation. Also retinitis pigmentosa and choked disc can be missed on an eye with high myopia while the fellow eye without high myopia shows the typical picture. Now in this Chinese the choked disc

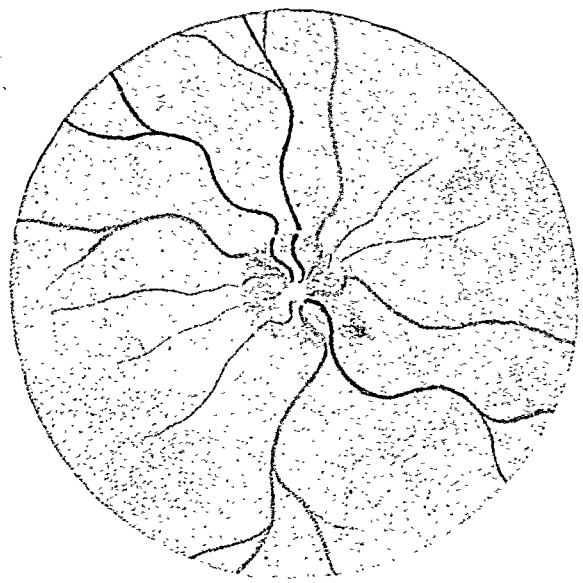

Fig. 4 (Fuchs). *Myopia inversa.* A common circumpapillary atrophy of the choroid was present in the right eye and the disc was indistinct but there was very little swelling. In the left eye, shown here, there was a large nasal atrophy of the choroid and a markedly choked disc.

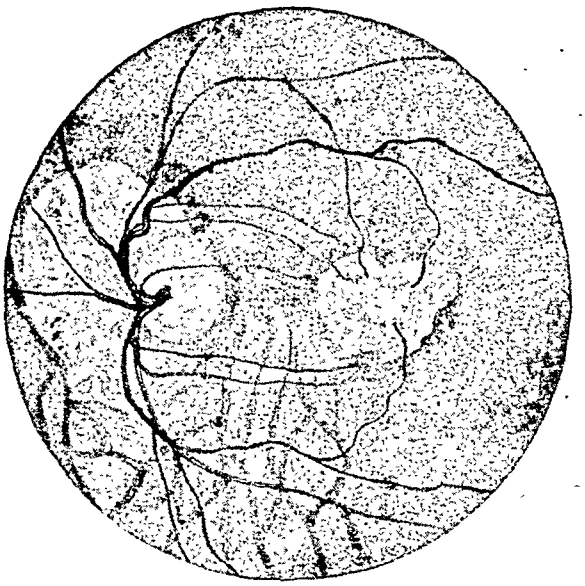

Fig. 5 (Fuchs). The case showed a big nasal atrophic zone of the choroid and a typus inversus vasorum on the left eye. In the fovea was situated a grayish focus (Fuchs's spot?).

was very much more conspicuous and easier to see on the left eye with the *nasal* atrophic zone than on the right eye with the high myopia and circumpapillary atrophy.

Pathologic changes in addition to myopia inversa I saw in two other cases many years ago in Vienna. The first case, that of a woman, 63 years of age, had a big nasal atrophic zone of the choroid and a typus inversus vasorum on the left eye (fig. 5). Below and on the nasal side, the fundus was albinotic while on the posterior pole and the temporal side the fundus was brownish. In the fovea there was a grayish focus, larger than the papilla. This focus was considered by some doctors as a coloboma of the macula while I thought it might be an old Fuchs spot because the patient had had better vision and had formerly complained of metamorphopsia. Vision was: −4D., 6/60-J5. Wassermann test was negative. We have

here a very large nasal choroidal atrophy although the myopia was not high at all.

The second case, that of an old man, was seen in the clinic of internal diseases and therefore an examination of the vision was

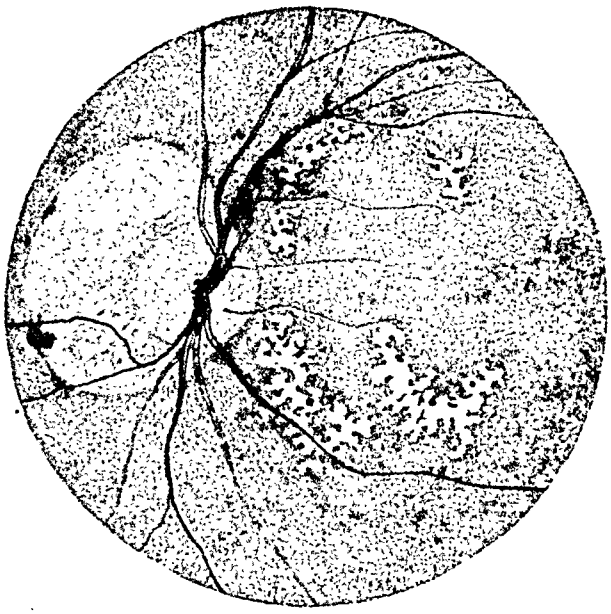

Fig. 6 (Fuchs). *Myopia inversa.* This myopic left eye showed a very broad atrophic zone of the choroid on the nasal side of the papilla and a retinitis circinata around the macula.

not made. The myopic left eye showed a very broad atrophic zone of the choroid on the nasal side of the papilla and a retinitis circinata around the macula (fig. 6).

7. Choroiditis proliferans

A very rare change of the fundus I called *choroiditis proliferans.*[13] It is characterized by a marked formation of connective tissue between retina and choroid. Narrow or broad strands (fig. 7) of whitish color and fine radiation are visible beneath the retinal vessels. Apparently the retina does not produce these strands because the vision is frequently quite good. According to my opinion, this connective tissue is a residue of a retinal detachment especially of an inflammatory detachment due to an exudative choroiditis. I imagine that in the fluid which is poured out between retina and choroid some filaments are formed by fibrin which later on become organized.

This idea was later on corroborated because there are numerous of these cases in China and I saw altogether about six cases of this type. The cause of the formation of the connective tissue in China is mostly Harada's disease which is by no means rare in that country. I saw a number of fresh cases of Harada's disease; some were very severe cases where retinal detachment was combined with deposits, severe iritis with infiltration, shrinkage of the vitreous, perfect blindness, and general symptoms. Some cases are very benign and show only a spontaneous detachment of the retina of short duration without other symptoms of the eye or of a general kind; one case healed in four weeks with final vision of 6/10.

The choroiditis proliferans in China, often monocular, shows the following symptoms: (1) Very long, thin, straight, white strands which are sometimes slightly bent, frequently branched, and sometimes end in a fan-shaped, fine striated connective-tissue layer. Frequently these white strands show knots like bamboo and they can also appear grayish and pigmented. (2) Frequently large areas of the choroid are covered with a thin membrane which hides the texture of the fundus and gives it a strange

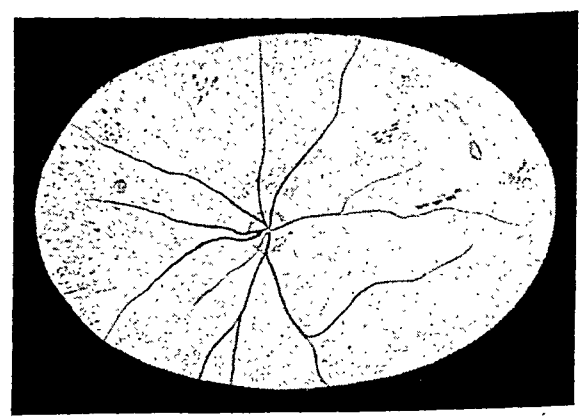

Fig. 7 (Fuchs). *Choroiditis proliferans* is characterized by a marked formation of connective tissue between the retina and the choroid. Narrow or broad strands of whitish color and fine radiation are visible beneath the retinal vessels.

silver-white color, while other parts of the fundus show the tesselated type of membrane (fig. 8).

Sometimes one can find in this whitish area a slight elevation of the retina of 1 or 2 diopters. In such a case the question arises as to whether in such an area the retina is detached or not. The visual field, especially the fact that the patient can see red and blue in this area, shows that there is no detachment and that the neuroepithelium is relatively intact. In spite of an extensive silver-white membrane, the function of the retina is not greatly impaired, and the vision can be relatively good.

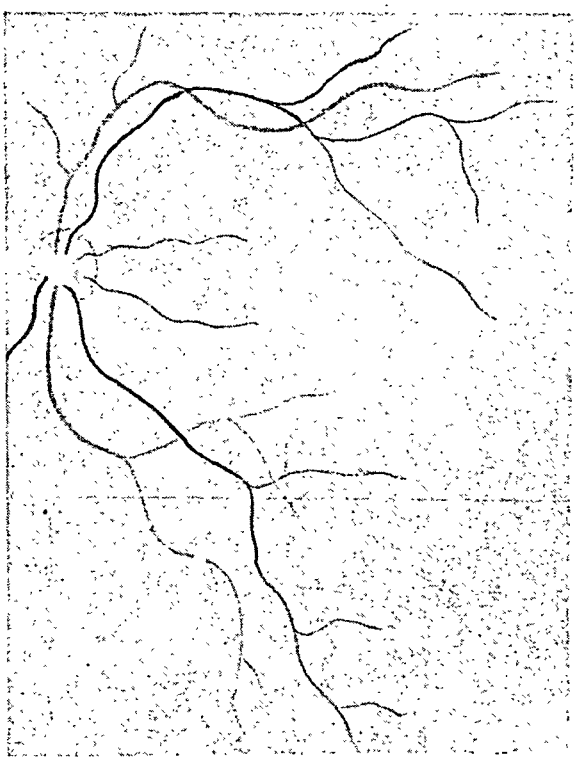

Fig. 8 (Fuchs). Frequently large areas of the choroid are covered with a thin membrane which hides the texture of the fundus and gives it a strange silver-white color, while other parts of the fundus show a tesselated type of membrane.

8. Neuritis retrobulbaris maligna

In China I found another new type of ocular disease which I could not find described in the available literature. This type I called *neuritis retrobulbaris maligna* and is characterized by a complete loss of vision in a very short time; in 2 to 3 days no light sensation or pupillary reflex on light remains. The fundus and especially the retinal vessels are normal. In Europe we have rare cases of retrobulbar neuritis with perfect loss of vision but an energetic treatment always seems to bring about a certain recovery and not so rarely the vision will become normal again. These Chinese cases differ from the European ones; in spite of energetic treatment the condition cannot be changed and the people remain blind.

The first case I saw was that of a Chinese general who had become blind in two days in both eyes and later on a genuine optic atrophy appeared. It was thought that the cause of this rather sudden blindness was intoxication with alcohol or another poison. The patient was examined in the United States by eminent doctors in a very intensive way but no diagnosis except optic atrophy could be made. I also could not imagine what was the cause, but I saw later a young man, aged 25 years, who became blind quickly in both eyes, and a woman, aged 39 years, who had the same condition in one eye. In these two cases, a genuine atrophy of the optic nerve followed and energetic fever therapy and injections of yatren-casein had not the slightest effect, and the pupillary reflex did not come back.

The important symptom which we generally find in cases of retrobulbar neuritis—slight sensibility of the globe when the eye is touched or moved—was present in all the three cases during the first days of the disease but only in a slight degree. So I learned by these two cases that the general had become blind apparently by the same disease as the two others, namely by a specially malignant retrobulbar neuritis.

This very rapidly developing inflammation of the optic nerve is without doubt combined with a very intense edema, because it seems that the edema compresses the nerve fibers in such a strong way that they are entirely paralyzed and the pressure keeps on for some time so that the

fibers lose their capacity to conduct the nervous impulse and cannot recover. I was not able to detect the etiology.

I have presented here some types of diseases which are either of clinical or of special scientific interest. In China, I was able to observe a few other new types of diseases but I have had no time, as yet, to work up my material.

Historical Miniature

In the times of the Greeks, Romans, and Arabs, and until the end of the European Middle Ages, all patients who had had successful surgery for cataract had to be content with the very moderate improvement in vision that was possible without cataract glasses. Sixteen-hundred years elapsed between the first description of cataract surgery by Celsus and of cataract glasses by Daça de Valdes, Notary of the Inquisition in Seville, in 1623. The lenses were numbered 11 or 12 for distant vision and 20 for near work. The numbers seem to correspond roughly to our diopters. The worthy notary does not reveal whether this was a new invention or how things were before, and he does not give evidence of the slightest comprehension of the refraction of rays in the aphakic eye.

Hirschberg, *Graefe-Saemisch Handbuch.*

OSTEOMA INVOLVING THE ORBIT*

FRANK W. NEWELL, M.D.
Chicago, Illinois

An osteoma is a benign tumor of non-inflammatory origin having a circumscribed form, a definite periosteal covering forming a line of cleavage from adjacent structures, and showing active participation of osteoblasts. The tumor commonly originates in a nasal accessory sinus and may invade the orbit relatively early in its growth, causing ocular disability prior to localizing signs in the sinus.

INCIDENCE IN LITERATURE

The many reports indicate that the tumor, while uncommon, is not rare. However, its incidence is difficult to assess as most reports deal with a single case, frequently one presenting bizarre symptoms or complications. The incidence of ocular involvement varies with the site of origin of the osteoma, being almost universal when original growth is in the sphenoid or ethmoid sinus, uncommon with frontal tumors, and extremely rare with those originating in the maxillary sinus. Unilateral exophthalmos arising from orbital tumors was found by Reese[1] to be caused by an osteoma but one time in 174 consecutive cases of surgically verified orbital tumors.

The male is affected more commonly. In Teed's[2] review of frontal sinus osteoma, 172 males were affected to 92 females, a figure corresponding closely to that determined earlier by Eckert-Mobius,[3] who found 110 males to 70 females. The preponderance of males is attributed by Armitage[4] to their greater liability to trauma and the larger size of their sinuses, which are, therefore, the site of greater developmental activity.

Extremes of age of 13 years (Carmody[5]) and 82 years (Blake[6]) have been reported. In Childrey's[7] series of 15 patients, the average age was 46.4 years, but only one case (Case 14) was symptomatic. In Teed's[2] review, the average age was 28.8 years, with 90 percent of the cases symptomatic. The age of the patient when first seen, however, gives little indication as to the time of occurrence because an osteoma may lie quiescent for long periods or reach huge size without symptoms.

The frontal sinus is the most frequent site of development. Malan[8] collected 458 cases; in 178, the growth occurred in the frontal sinus; in 110, in the ethmoid sinus; in 41, in the maxillary; and in 7, in the sphenoid sinus. In the remainder the growth was external, of doubtful origin, or it was questionable as to the first cavity involved.

GROUPS OF OSTEOMAS

True osteomas may be divided into three main groups: the eburnated, which is ivory hard; the compact, which has a structure not unlike that of normal bone; and the spongiose, which represents the most immature type. Externally they present a hard, glistening, rounded surface with numerous facets following the outlines of the sinuses and structures impinged against during the period of growth. They may be sessile with a broad base of spongiose bone, or they may have a pedunculated base of compact bone.

Microscopically, the tumor is covered with well-defined, apparently normal periosteum, with branches extending into the substance of the growth. The eburnated type consists of solid bone without haversian canals and with the bony lamellae arranged in whorl formation. The compact type presents an exterior not unlike the eburnated type, but interiorly, small haversian canals are present, surrounded by concentric rows of

* From the Departments of Ophthalmology, University of Minnesota, and Northwestern University Medical School.

bony lamellae with irregular arrangements of bony corpuscles in bundles. The spongiose type consists largely of connective tissue with large numbers of fibroblasts and numerous interconnected areas of new-bone formation.

It is most important that the tumor be distinguished from the most common cause of bony hyperplasia of the bones of the skull, namely, the hyperostosis occurring in the course of dural endothelioma. Dandy,[9] who states that he has never seen a localized osteoma, warns that the hyperostosis of meningioma is so common that a degree of skepticism is warranted when a diagnosis of pure osteoma is made. Microscopically, this type of hyperostosis shows the marrow spaces of the bone filled with tumor cells, the invasion of which causes the bony overgrowth.

Theories of cause

Numerous theories have been advanced as to the cause of osteoma, none of which adequately explains its occurrence in each of the nasal sinuses. Arnold[10] believed that the tumor represented ossification of the fetal cartilage at the junction of the ethmoidal and frontal sinus where bone of endochondral and membranous origin were adjacent.

Ersner and Saltzman[11] likened the formation to osteomyelitis where, according to Mosher,[12] osteoblastic and osteoclastic activity take place simultaneously. They considered a low-grade exudative infection in the sinuses might stimulate osteogenesis more than osteoclasis and result in bony tumor formation.

Cushing[13] believed the tumor might be initiated by a fissured fracture of the anterior cranial fossa with a diastasis of the suture between the orbital plate of the frontal bone and the adjacent edge of the ethmoid bones roofing the ethmoidal cells, causing quiescent cartilage to be stimulated to bone production.

Fetissof,[14] who supported his contention with histologic studies, advanced the theory that the tumor initiated from a nest of periosteum split of bone at an early age, which developed a tumor under the influence of irritation and trauma.

Symptoms and signs

Symptoms and signs of osteoma may be conveniently divided into cerebral, nasal, and ocular groups with the predominant type dependent upon the site of origin and with many growths asymptomatic. Cerebral disturbances are uncommon and include mental deficiency, vertigo, various sensorimotor disturbances, convulsions, cerebral pneumatocele, and signs of increased intracranial pressure.

Sphenoidal growths almost universally give rise to intracranial difficulties because of their location, which makes their removal an extremely formidable procedure. Meningitis and brain abscess have occurred following surgery, particularly in cases reported in the preantiseptic days. Cerebrospinal rhinorrhea may complicate surgery of an ethmoidal tumor and is observed rarely preoperatively.

Occlusion of a sinus with resultant infection occurs most commonly in tumors of the frontal sinus because of their predilection for growth at the inferior nasal angle of the sinus. Obstruction of breathing on the side of the tumor is uncommon and occurs most commonly in osteoma of the ethmoid. Anosmia usually indicates cerebral extension with involvement of the olfactory nerve at the christa galli. Fenton[15] reported one case of well-defined nasociliary neuralgia being relieved by removal of a small osteoma of the frontal sinus which was impinging on the anterior ethmoidal nerve.

Ocular signs occur most commonly with ethmoidal and sphenoidal tumors. The ethmoidal type are so likely to extend into the orbit that Cushing[13] labeled them "orbito-ethmoidal" osteomas. Orbital extension usually results in a slowly progressive exophthalmos which, if untreated, may cause loss of the globe.

Fridenberg[16] reported a case in which growth of the tumor from the central portion of the frontal sinus caused an enophthalmos. Rarely, orbital extension from the frontal or ethmoidal sinus causes displacement of the trochlea with signs of superior oblique paresis, a complication which may follow removal of the tumor.

Sphenoidal osteomas tend to involve the optic nerve early, with visual disturbance and optic atrophy, and, rarely, papillitis or papilledema. Occasionally an ethmoidal tumor will cause papillitis, presumably due to involvement of the optic-nerve blood supply.

Diagnosis

The diagnosis is based upon roentgenographic evidence of a well-circumscribed, bony tumor originating in a sinus and the absence of increased thickness of other bones of the skull. Usually there is no question of the diagnosis of the frontal or maxillary-sinus osteoma as the appearance of a localized, isolated bony sphere resting on the floor of the sinus is quite characteristic.

Diagnosis of the sphenoidal tumor can be made with certainty only by microscopic study of the tumor, as dural endothelioma may give rise to a similar picture. This is true, but to a lesser extent, of tumors originating in the ethmoid sinus, although a localized, well-circumscribed bony tumor occurring here without evidence of hyperostosis of the roof of the orbit or sphenoid ridge is most likely an osteoma.

Dandy[17] points out that the age of the patient is an important differential point as dural endotheliomas occur after the age of 30 years and the benign osteoma frequently occurs before. He warns that the burden of proof must rest on the diagnosis of osteoma when made after the age of 30 years.

Treatment

The treatment is surgical but the opportune time and surgical approach have been much debated. Those occurring in the frontal and maxillary sinus frequently remain asymptomatic for long periods and, in the absence of symptoms or rapid growth, surgery is not indicated.

Sphenoidal tumors should be removed immediately, if possible, for the slow but gradual growth will ultimately result in blindness and death. The likelihood of bony tumors in this location being part of the hyperostosis of meningioma is indication enough for the surgery other than their bad prognosis even though histologically benign.

Ethmoidal tumors, because of their early encroachment into the orbit, frequently require early surgery but, in the absence of symptoms or rapid growth and with the patient less than 30 years of age, some procrastination is permissible. Operative intervention will, however, likely be necessary.

The ethmoidal tumors may be removed by an anterior orbital route or by Cushing's osteoplastic transtemporal approach. The anterior route is preferred in cases of well-circumscribed tumors lying far forward in the orbit and in the absence of signs of cranial extension. The transtemporal approach must be used in sphenoidal tumors, those with intracranial extension, and questionable growths possibly secondary to meningiomas. The frontal and maxillary sinus osteomas are probably best removed through an external approach over the involved sinus. Radium and X-ray therapy was successfully used in two cases of spongiose osteoma of the maxillary sinus by Priest and Boies,[18] but was of no value in Case 3 of this series.

Case reports

Case 1

History. The patient, a 24-year-old, white, unmarried farmer, was first seen January 15, 1942. He complained of progressive protrusion of the left eye, of three years' duration. There was no history of trauma and the patient was in good general health except for frequent left frontal headaches relieved with aspirin. He had had the usual childhood dis-

eases and the past history was essentially irrelevant.

Examination. Vision was 20/20 in the right eye and 20/25 in the left eye, improved to 20/20 with a −0.5D. sph. ⊂ +1.5D. cyl. ax. 75° correction. There were 4 prism diopters of exophoria for near and far (Maddox rod) and no hyperphoria. The extraocular movements were normal and the convergence near point, 50 mm. The exophthalmometer (Hertel) reading was: R.E., 18 mm.; L.E., 28 mm. The pupils were equal and reacted normally to light and accommodation. The closed lids did not entirely cover the left eye. At the left inner canthus a hard, fixed, smooth nodule, firmly adherent to the bony orbit, was palpable. Ophthalmoscopic examination showed normal fundi and the peripheral and central fields were normal. Roentgenologic studies showed a dense, bony mass encroaching upon the left orbit, apparently arising from the floor of the left frontal sinus adjacent to the ethmoid plate.

Fig. 1 (Newell). *Case 1.* X-ray study of ethmoidal osteoma involving left orbit.

Operation. On January 16, 1942, under ether anesthesia, an incision was made from the inferior medial angle of the orbit, upward to a point 10 mm. above the insertion of the medial canthal ligament. The ligament was severed, the bony tumor exposed and chiseled free of its insertion in the ethmoid and floor of the frontal sinus. The tumor was then grasped with a rongeur, rocked free, and extracted from the wound.

A large defect in the left frontal sinus was created and a large amount of white, glistening, tenacious mucous removed. There was no evidence of cerebrospinal fluid, and no defect was found in the anterior cranial fossa.

The wound was packed with sulfathiazole powder, the medial canthal ligament was sutured to its original insertion, the wound closed with interrupted black silk sutures, and a compression dressing applied. The first seven days postoperatively, the patient received 4 gm. of sulfadiazine daily. His temperature did not exceed 100°F., the convalescence was uneventful, and the patient was discharged the 12th postoperative day.

The osteoma was a characteristic eburnated type and measured 36 by 32 by 25 mm. It weighed 21.5 gm., and arose from the ethmoidal sinus and invaded the frontal sinus secondarily.

Result. The patient was last seen on March 9, 1942, at which time the eyeball had receded to normal position. There was orthophoria for near and far. Vision was 20/20 in each eye without correction. There was a paresis of the left superior oblique muscle and a diplopia with the red glass on looking down and to the right. The patient was not troubled with this diplopia, and in a recent communication he stated that it is no longer present.

CASE 2

History. The patient, a 22-year-old, white, unmarried farmer, was first seen August 12, 1921, complaining of marked tearing of the right eye the previous four weeks. There had been no improvement of the condition with lacrimal-sac irrigation by his family physician. Past history revealed smallpox in February, 1921, and no history of trauma or nasal infection.

Examination. Vision was 20/20 in each eye, uncorrected. The ocular movements and pupillary reactions were normal. The patient was unable to converge, and there were 12 prism diopters of exophoria for far and near. The lacrimal sacs were irrigated with ease.

One month later the patient noted a small nodule at the inner canthus of the right orbit and X-ray study showed a dense tumor arising from the lateral wall of the ethmoidal labyrinth, invading the orbit and the frontal sinus on that side. In October, 1921, the patient noted divergence and diminution of vision of the right eye.

When the patient was seen on November 18, 1921, there was a right divergent squint of 10 degrees, a palpable tumor at the inner canthus, and a papillitis with elevation of the disc, 2 diopters. Vision was 20/70 and could not be improved. There was no exophthalmos and neurologic examination was negative.

Operation. The tumor was removed by Dr. Frank E. Burch. The postoperative course was uneventful, and the patient was discharged the 11th postoperative day. The osteoma was of the eburnated type with a broad base of cancellous bone attached, apparently, to the lateral wall of the ethmoidal labyrinth. It measured 25 by 29 by 31 mm.

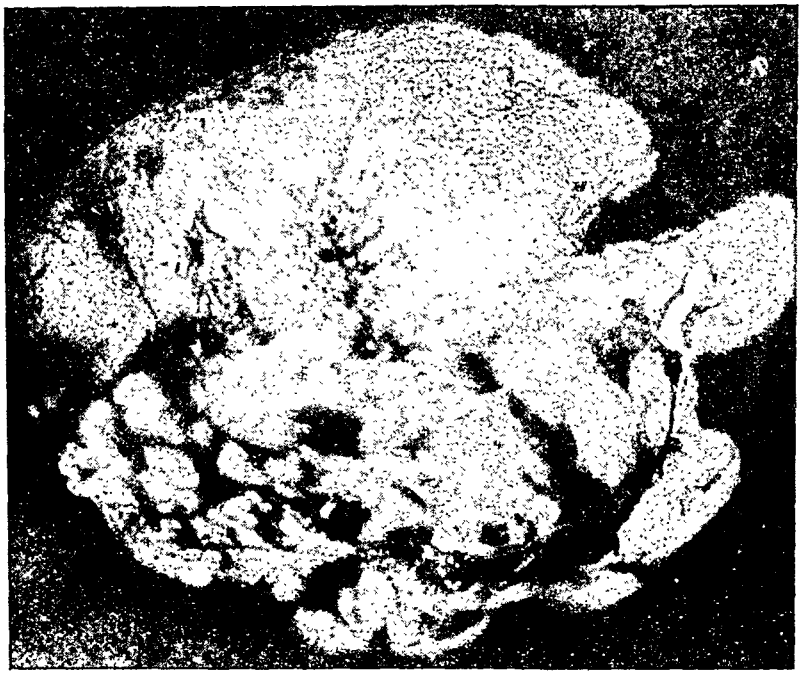

Fig. 2 (Newell). *Case 2.* Appearance of tumor; the rough, irregular surface is the pedicle which was attached to the ethmoidal sinus and the smooth area represents the orbital extension.

Course. When seen in August, 1942, there had been no recurrence. The eyes were parallel and the patient was able to converge slightly. Vision was 20/20 in each eye without correction, and there was an exophoria

of 4 prism diopters for far and near.

Comment. Case 1 presents a typical history and symptom complex, as has been reported in most cases of ethmoidal osteoma. Slowly progressive exophthalmos was the only sign with no signs of involvement of the nose or central nervous system. The almost directly lateral growth of the tumor in Case 2 caused a divergent squint rather than a proptosis.

The exophthalmos in Case 1 and papillitis with diminution of central vision in Case 2 necessitated immediate surgical intervention. In each case the anterior orbital approach yielded a gratifying result; with antibiotics and sulfonamides now available, the danger associated with the exposure of the dura to infection is much minimized.

CASE 3

History. The patient, a 10-year-old, white school-girl, was first seen July 10, 1928,

Fig. 3 (Newell). *Case 3.* Appearance of exophthalmos when patient was first seen in July, 1928.

complaining of a proptosis of the right eye, which had first been noted in March, 1926. There was no other complaint, no pain, and the exophthalmos did not appear to be progressive. Past history revealed the usual childhood diseases, including scarlet fever.

Examination. Physical and laboratory examinations were essentially negative. Vision was 20/40 in the right eye and 20/20 in the left, without correction. She was orthophoric for near and far, and extraocular movements were normal. A hard mass was palpable at the external canthus of the right orbit. Exophthalometer (Hertel) reading was: R E., 24 mm.; L.E., 15 mm. Ophthalmoscopic examination was normal.

Roentgenographic studies of the skull showed a dense, round mass which nearly filled the right orbit. The roentgenologist believed that it originated in the inferior, posterior portion of the orbit and stated it had the appearance of an osteoma.

X-ray studies four months later demonstrated an increase in size of the tumor, with likely origin in the sphenoid sinus. When examined on November 20, 1928, vision was 20/70 in the right eye and could not be improved. A definite papillitis was present.

Course. From November 28, 1928, until September 16, 1930, she was followed at the Mayo Clinic and received deep X-ray and radium therapy to the right orbit. She was seen again on May 6, 1931, at which time the right optic nerve showed complete atrophy, the proptosis had progressed, and she had been having convulsions once or twice a week the previous seven months. During the following year the patient again received deep X-ray treatments to the right orbit and radon needles were implanted in the orbit.

The tumor continued to increase in size, and the proptosis became so marked that an exposure keratitis necessitated removal of the eye in June, 1933. During this procedure the anterior portion of the bony mass was removed and studied microscpically. The bone chips had the structure of a compact

osteoma, and there was no evidence of malignant cells in the marrow.

In July, 1933, vision in the remaining eye was reduced to 5/200 and a definite papilledema was present. Convulsive seizures were more frequent and there was mental deterioration. It was assumed that an internal hydrocephalus was present. The patient died at home in October, 1933; unfortunately, an autopsy was not obtained.

Comment. The signs and symptoms of this little girl were characteristic only of an orbital and cranial space-occupying lesion, and diagnosis was dependent largely upon roentgenographic evidence. The age of the patient, slow growth of the mass, and absence of other signs served to differentiate the tumor from a meningioma, as did the study of the anterior face of the growth. The patient was, incidentally, younger than any other previously reported with osteoma. The extensive involvement of the sphenoid bone when the tumor was first discovered made surgery almost impossible, although her tragic end makes operative intervention, however apparently hopeless, seem worthwhile.

CASE 4

History. The patient, a 26-year-old, white, married salesman was first seen on February 12, 1932, complaining of diplopia since February 7th, when he acquired a mild upper respiratory infection.

Examination. He had been examined by an oculist in August, 1931, and a 3-diopter prism base up had been incorporated in his right lens. Vision was 20/70 corrected to 20/20 in each eye. There was 17 prism diopters of left hyperphoria and one prism diopter of exophoria with a vertical diplopia in all directions of gaze. No limitation of extraocular movements could be demonstrated. Peripheral and central visual fields and the fundi were normal. X-ray studies of the sinuses showed an osteoma of the inferior medial angle of the left frontal sinus measuring 5 by 10 mm.

The patient was examined two weeks later, at which time there were 2 prism diopters of left hyperphoria and no diplopia. He has been seen intermittently since that time and, when last examined, on February 24, 1942, he had a left hyperphoria of 11 prism diopters. Corrected vision has remained 20/20 and there has been no change in the fields or fundi. X-ray studies during this period have demonstrated no increase in size of the tumor, and there have been no nasal or cerebral symptoms.

Fig. 4 (Newell). *Case 4.* X-ray study of involvement of the right orbit with a sphenoidal osteoma.

CASE 5

History. The patient, a 20-year-old, white, unmarried woman, was first seen on July 17, 1934, complaining of severe, right frontal headaches following close work.

Examination. Vision was 20/30 and 20/50, right and left, respectively, corrected to 20/20. There were 4 prism diopters of exophoria for far and 8 for near, with no hyperphoria. A slight right ptosis was present. Visual fields were of bizarre conformation and were considered unreliable. Ophthalmoscopic examination showed no abnormalities.

Roentgenographic studies showed the complete absence of the left, frontal sinus and, arising from the inner angle and floor of the right frontal sinus, was a dense, bony mass extending downward along the medial wall of the orbit. Neurologic examination revealed a marked hyperesthesia of the right frontal region, which followed no definite nerve distribution.

Course. When subsequently seen, a marked spasm of accommodation was present, which was not relieved until after daily use of atropine for three weeks. Following this, the headaches disappeared but the hyperesthesia of the forehead persisted. The patient refused surgery and has not been seen since August, 1936, at which time her condition was unchanged.

Case 6

History. The patient, an 18-year-old, white, unmarried, young man, was first seen on August 2, 1934, complaining of severe arthritis involving the shoulders, hips, back, and knees. In routine X-ray examination of the sinuses for possible foci of infection, an osteoma of the lateral portion of the left frontal sinus was demonstrated and ocular examination advised.

Examination showed no abnormality of vision, fields, fundi, or ocular movements. The tumor has not increased in size since the patient was first seen, and he has no complaints referable to the nose, eyes, or nervous system.

Case 7

History. The patient, a 23-year-old, white, unmarried soldier, was first seen on February 14, 1946, complaining of a right convergent strabismus, which had been present since childhood. Previous history revealed no abnormalities, and physical examination was negative.

Examination. A routine sinus X-ray examination prior to ocular surgery revealed an osteoma of the right frontal sinus measuring 2½ by 1 cm. Neurologic examination and complete ocular examination revealed no abnormality other than an alternating convergent strabismus, which was corrected with surgery.

Comment. Case 4 and Case 5 are difficult to analyze because of the bizarre and variable symptoms which cannot be attributed to the osteoma. Case 6 and Case 7 are typical of most frontal sinus osteomas which are discovered on routine examination and seldom, if ever, give rise to symptoms.

Summary

Seven cases of osteomas are presented; in 2 cases the tumors arose in the ethmoidal sinus, in one in the sphenoid body, and in 4 in the frontal sinus. The tumors arising in the ethmoidal sinus were removed successfully, while the sphenoidal osteoma which was considered inoperable resulted in death of the patient from an internal hydrocephalus.

THE ANTITRACHOMA CAMPAIGN IN JEWISH SCHOOLS OF JERUSALEM

BELLA MIRENBURG, M.D.*
Jerusalem, Palestine

About 30 years ago, Jewish physicians of Palestine, realizing the danger that, owing to the wide spread of trachoma, threatened both the Jewish population that had already settled in the country and the new immigrants, constituted the first antitrachoma committee. As a result of its activities, trachoma is at present but a minor issue among the many medical problems facing the Jewish authorities.

Trachoma means no longer a danger to the health of the Jewish people of Palestine —a fact that is all the more important in view of the high incidence of trachoma in all countries of the Near and Middle East, in spite of the greatest efforts being made everywhere to tackle the problem.

For example in Egypt an antitrachoma campaign was launched by the government 40 years ago and has ever since been continued with the assistance of other institutions which realized the urgency of the task. However, according to the yearly report issued by the health bureau in Cairo, almost 99 percent of pupils in schools were found affected in 1939. Since that time (according to a personal communication received by the Hadassah Medical Organization from Dr. Wilson, head of the Antitrachoma Service in Egypt, in 1944) no progress has been made and even now practically every single pupil has the disease with the exception of a very small percentage (0.5 to 1.5 percent) belonging to the well-to-do classes.

In Palestine, too, besides the Jewish Antitrachoma Service, several institutions (missions, and others) have assisted the government in its endeavors to meet the danger of trachoma in the country. But, according to a report of the Government Health Office in Jerusalem, in 1939, more than 39 percent of pupils in government schools in Jerusalem were infected at that time, and there is no reason to believe that during the war years, conditions were improved.

In Jewish schools, however, owing to the unrelenting efforts of the physicians engaged in this strenuous work, and the energetic war against trachoma waged by the Hadassah Medical Organization, the systematic and intensive treatment given to every single case has yielded remarkable results. In 1918, at the time when antitrachoma work was started by this organization, the per-

* Physician in charge of antitrachoma, Department of Hadassah. Because the mails to Jerusalem are closed the author has had no opportunity to read proofs of this paper.

centage of active trachoma in Jerusalem among all pupils supervised, was 21.6 percent. This percentage had dropped to 1.8 percent by the winter of 1942-1943, and is now 1.4 percent.*

During the early stages of its activities the antitrachoma committee confined its services to Jerusalem schools, gradually widening its scope and including Jewish schools of other towns, eventually extending to the rural settlements, too.

The aim of this campaign was twofold and consisted, first, of prevention of a further spread of the disease among the population and, second, of the treatment of affected persons. Once or twice a year every single child is examined by an experienced ophthalmologist and, when a high rate of infection is found, the school is immediately placed under supervision, the pupils being from then on examined at monthly or bimonthly intervals. The treatment of infected children lies in the hands of specially trained nurses who visit the schools every day. If corneal complications are detected, the child is immediately presented to the school doctor or sent to the ophthalmologic clinic for treatment.

The routine therapy of trachoma in our schools consists of instillation of a 5-percent copper-sulphate solution (we prefer a solution that has been standing for some time) in combination with zinc-resorcin and frequent expressions for cases of active trachoma; while in inactive cases, a 2-percent copper-sulphate solution is used with zinc resorcin.

In the course of time it was realized that in order to eradicate the disease it is not sufficient to treat a child in whom the infection is accidentally found, for it occurred all too often that a child, after having once been successfully treated, was reinfected at home. Treatment had, therefore, to be extended to the families, too, and, in 1926, clinics were opened by the Hadassah Medical Organization to deal with that part of the population. How successful this procedure was appears from the fact that, for example, in the clinic of the Old City of Jerusalem which opened with 757 cases among a total of 2,237 Jewish inhabitants, the number of infected cases is now no more than 12 among a population that has meanwhile grown to 3,000.

The antitrachoma service is being effectively assisted by the health welfare nurses attached to the schools under supervision by the Hadassah Medical Organization and to the health welfare centers established all over the city. The ophthalmic and welfare nurses do not confine themselves to the treatment of the sick child but also visit the child's family and take care of sanitary conditions in his home.

An important factor greatly contributing to the satisfactory results of the antitrachoma campaign is the systematic care children are now receiving from the day they are born, and during their entire childhood by the health welfare centers. As soon as trachoma is detected there, the child is immediately given the necessary treatment. When he begins to attend kindergarten, he is either completely healthy or at least greatly improved. Thus statistics compiled for kindergarten children in Jerusalem for the years 1942-1943 show a percentage of no more than 1.3 for active trachoma (21 cases among 1,725 children).

The physicians engaged in antitrachoma work know that they are social workers and that their success depends in the same measure on the treatment of the individual case as on the degree to which they are able to reach the population by instruction. Of course, much depends on the social standard and adaptability of the various population groups and it is not surprising that results are not uniform in all communities. The majority of trachoma cases, as regards the Jews, is now concentrated in the oriental communities which, generally, have a lower social, cultural, and hygienic standard. Un-

* These figures refer to schools as a whole comprising all Jewish communities.

fortunately, no data are obtainable on the distribution of the various Oriental-Jewish groups in Jerusalem schools. We are, however, in possession of data concerning the distribution of children aged 5 to 14 years by community in the Jerusalem population at large (census of the Jewish Agency of 1939). In the attached table a calculation has been made—on the basis of these data and the occurrence of trachoma in schools—of trachoma incidence per 1,000 children in each community at the ages mentioned above.

From Table 1 it appears that the highest percentage of cases is found in Persian Jews and the lowest in Ashkenazic Jews. As to the sexes, there is practically no difference. As regards age, the incidence of trachoma in the oriental communities rises up to the age of 10 years, and drops after that age.

TABLE 1

TRACHOMA INCIDENCE PER 1,000 CHILDREN

Community*	Per Mille Trachoma	No. Cases
Persians	50.8	90
Kurdians	48.4	66
Babylonians	48.1	87
Georgians	22.1	8
Bokharians	20.1	11
Syrians	12.2	7
Yemenites	11.1	11
Maroccanians	8.6	6
Sephardic Jews	5.0	14
Ashkenazic Jews	1.0	6

* All these are Jewish communities.

This is in accordance with the view held by the majority of investigators who consider trachoma a disease of childhood, especially where it is endemic.

As a result of the steady drop in trachoma cases, the number of children under treatment for active trachoma was no more than 307 in winter 1942 to 1943; and for inactive trachoma it was 331 of 17,533 children for the corresponding periods. The cases are, moreover, usually mild and pannus or trichiasis have altogether disappeared from among our children.

TABLE 2

DISTRIBUTION OF TRACHOMA IN JEWISH SCHOOLS OF JERUSALEM BY AGE

Age (Years)	Trachoma Cases per 1,000 Children in Jerusalem Schools
4–6	23.0
6–8	28.8
8–10	36.8
10–12	29.4
12–14	9.5
14–16	4.3

From the tabulation in Table 4, it appears that the highest percentage (6.6 percent) is found in the evening classes; that is, among children that may not have had any schooling at all during their younger years. The figures should, therefore, be accepted with certain reservations, since they may also refer to children who have attended schools outside the supervision scheme during their earlier years.

TABLE 3

DECREASE OF ACTIVE TRACHOMA IN JEWISH SCHOOLS OF JERUSALEM FROM 1918 TO 1946

Year (Winter)	Cases of Active Trachoma per 1,000 Pupils Under Supervision
1918/19	21.6
1920/21	21.4
1921/22	18.3
1922/23	13.9
1923/24	13.1
1924/25	11.5
1925/26	9.5
1926/27	14.2
1927/28	13.0
1928/29	11.2
1929/30	11.9
1930/31	9.4
1931/32	8.5
1932/33	7.4
1933/34	3.9
1934/35	3.2
1935/36	2.9
1936/37	2.1
1937/38	4.9
1938/39	4.1
1939/40	3.0
1940/41	1.8
1941/42	1.9
1942/43	1.8
1943/44	2.1
1944/45	1.6
1945/46	1.4

During the past few years it has been tried, therefore, to extend ophthalmic supervision to children of postschool age (evening classes of several youth organizations), and three of Hadassah's ophthalmic nurses have been placed at the disposal of this new service. Moreover, in summer during the school vacations, centers are opened all over the town, where trachoma and acute eye inflammation are treated and to which almost 90 percent of the children come every day.

TABLE 4

DISTRIBUTION OF 307 CASES BY TYPE OF SCHOOL ATTENDED

Type of School	Trachoma Cases per 100 Pupils
Evening classes, etc.	6.6
Talmudei Torah (religious schools)	3.1
Elementary Schools Affiliated with the Education Department of the Jewish National Council	1.2
Elementary Schools Not Affiliated with the Education Department	0.6
Secondary Schools and Teachers' College	—
Kindergartens and Day Nurseries	1.3

Special problems are facing the antitrachoma services in connection with the expected immigration. The arrival of the so-called "Teheran children"* and groups of immigrants from oriental countries (Algiers, the Yemen, and so forth) have taught us a lesson. We must be prepared to wage a renewed war to free this country from the disease, as far as this is possible, and our success depends entirely on the degree to which it will be possible to extend this struggle to the country as a whole and to all parts of the population, Jews and Arabs alike.

Thanks are due to Prof. R. Bachi, head of the Central Bureau of Medical Statistics, and Dr. G. Kallner for their kindness in preparing the statistics.

Gan-Rehavia.

* Jewish refugee children from Europe, usually without parents, who had drifted about for many years before they reached Palestine, their last station being Teheran.

HISTORICAL MINIATURE

Fabricius ab Aquapendente, in 1600, was the first to publish an illustration that correctly shows the position of the lens. Leonardo da Vinci (1452-1519) approached the truth very closely, but his drawings were not published until late in the nineteenth century.

Hirschberg, *Graefe-Saemisch Handbuch.*

FRIEDLÄNDER'S BACILLUS INFECTION FOLLOWING PERFORATING WOUND OF ORBIT*

Report of a case treated with streptomycin

Walter J. Crawford, M.D.
Riverside, California

Friedländer's bacillus infections are unusual. Extensive search of the literature has revealed no previous reports of perforating injury of the orbit, maxillary sinus, and nasopharynx complicated by infection with this bacillus. The case to be reported here developed an orbital cellulitis. Although in reviewing the literature, there were several cases of suppurative sinusitis caused by this bacillus,[1,2] there was only one earlier report of an orbital cellulitis.[3,4]

Dr. Carl Friedländer[5] isolated this bacillus, in 1882, from the lungs of a fatal case of pneumonia and called it Pneumoniecoccus. It was later called Klebsiella friedländeri, Klebsiella pneumoniae, Bacillus mucosus capsulatus, or Bacillus friedländeri.[6]

Recent writers, among them Baehr and his associates[1] and Jaffee,[7] have mentioned this confused terminology and suggest that this organism be called either Klebsiella friedländeri or Bacillus friedländeri. Bergey[6] prefers Klebsiella pneumoniae.

Friedländer's bacillus is a gram-negative, encapsulated rod, varying in size from 0.3 to 0.5 by 5.0 microns, occurring singly and in pairs. It is nonmotile and does not form spores. It usually produces smooth, mucoid, cream-colored, raised colonies on blood agar at from room temperature to 37°C. Hemolysis does not occur but the plate is browned. In broth its growth is turbid, and a ring or film is found at the top of the tube or flask. Numerous fermentation and other differential tests have been suggested and used;[8] however, until Julianelle's classification[8,9] of the Friedländer group into serologically separate types, its recognition was often uncertain.

A recent article by Osterman and Rettger[10] states, "Valid criteria have not yet been established for the differentiation of the organisms of the Friedländer and coli-aerogenes groups." Friedländer's bacilli belonging to Type A of Julianelle's classification may be identified with considerable certainty. Organisms in Type B (which is immunologically similar to, although not identical with, Type II pneumococcus[8]) and Type C (which is identical with the Rhinoscleroma bacillus[11]) may be identified with some certainty. The rest of the group, classified in a heterogenous group X, remains ill defined.

The frequency with which the different serologic types of Friedländer's bacilli are encountered was studied by Julianelle[12] who, working with 80 strains, found 52 percent to be Type A; 15 percent, Type B; 9 percent, Type C; and the remaining 24 percent were considered to be in the heterogenous group X.

It is difficult to discuss the incidence of Friedländer's bacillus infections, since accurate identification was not always made in early cases, nor even in all the later ones. The incidence of these bacilli in the upper respiratory tract of normal persons was reported as 5.8 percent.[13] This figure has been used by numerous authors; however, more recent investigators[1] doubt this percentage of incidence and believe that, on the rare occasions when it is found and accurately identified in the upper respiratory tract, it is present as a contaminant from the intestinal tract where it is reliably found in 5.5 percent of normal persons.[1,14]

The mortality of Friedländer's bacillus in-

* From the Division of Ophthalmology, University of California Medical School. Acknowledgement is made of the technical assistance of Sarah R. Crawford, B.A., and of the valuable advice of Dr. Phillips Thygeson. This work was done with funds from the Mr. and Mrs. Berthold Guggenhime donation.

Fig. 1 (Crawford). Appearance of patient when hospitalized, showing proptosis, whitish exudate, injection, chemosis, and the papilloma.

fections is difficult to estimate. Prior to chemotherapy the prognosis was poor in all cases. In a review of 232 cases of Friedländer's bacillus pneumonia, the mortality was 94 percent.[8] Of the 198 cases of Friedländer's bacillus infections reported by Baehr and his associates,[1] biliary tract infections had a mortality of 30 percent; urinary tract infections, 17 percent; Friedländer's septicemia in the same series, 75 percent. The mortality varies with the type of the organism encountered as well as with the site of the infection. Of the three distinct serologic types, Type A is the most virulent and Type C, the least virulent, for both human beings and mice.[9,10] The pathogenicity of the heterogenous group X is ill defined.[10]

Report of a case

History. The patient, S. P., was first seen at this clinic on February 11, 1947, with a history of having been jabbed two months previously (December 11, 1946) with a pencil which had penetrated the outer portion of his left upper lid. He reported that he had been intoxicated at the time but remembered that there was immediate pain as well as transitory bleeding. The patient stated that the pencil had penetrated to a maximum depth of one-half inch and was certain that it had been withdrawn immediately. He was treated by his local physician for the ensuing "red eye" with one of the sulfa drugs orally, until he was referred to this clinic. Some temporary clearing had been noted approximately the 3rd or 4th day after the injury.

From February 11 until April 3, 1947, when he was admitted to the hospital here, the patient was seen every week or every other week. He was not seen more frequently because he lived a considerable distance away and was short of funds for transportation and board.

Examination. On the patient's initial visit, examination revealed a diffusely injected, thickened, beefy-red conjunctiva; a scanty whitish exudate, a papillomatous mass in the lower fornix, moderate edema of the lids, and slight proptosis of this left eye. Since the patient was positive on repeated questionings by various staff members that the pencil had been withdrawn, laboratory investigation was resorted to.

Smears taken at this time were later reported to contain many neutrophiles, occasional gram-positive cocci, and a few gram-negative rods. The total white blood-cell count was 12,900 and the Kahn and Kolmer tests were negative. The Frei test was doubtfully positive. On initial cultures a few colonies of Streptococci viridans were found as well as numerous colonies of diphtheroids, and a moderate number of colonies of Friedländer's bacilli which gave the characteristic "quellung" reaction with Type-A serum.

Treatment. Sulfathiazole treatment, 1 gm. orally every 3 hours while awake, had been started as the organisms causing the patient's

Fig. 2 (Crawford). Closeup of left eye.

posttraumatic infection were unknown at the time.

The papilloma was excised February 14th, and streptomycin ointment was prescribed for local use because of the Friedländer's bacilli; streptomycin was not used systemically as the patient could not be hospitalized. Sulfadiazine was given instead of sulfathiazole since it was believed to be less toxic. Because of the doubtfully positive Frei test, mice brains and chorio-allantoic membranes were inoculated and 300,000 units of penicillin in beeswax were given on two successive days. The egg and mouse-brain inoculations were reported negative for viruses. Orbital X-ray films, taken on February 19th, were reported negative.

Course. When the patient was seen again, the conjunctiva showed some slight clearing but the papilloma had recurred. Otherwise, his condition was unchanged. Smears and cultures were essentially the same.

In the middle of March, stereoscopic views of both orbits, as well as sinus plates, were made. These X-ray studies were negative except for some slight clouding of the frontal and maxillary sinuses. At this time, also, the papilloma was reëxcised. The report of the first biopsy had been: "Nonspecific infectious granulation tissue."

Since cultures had become negative for any organisms other than Friedländer's bacillus—Type A, it was decided to admit the patient to the hospital for systemic treatment with streptomycin, which is reported

Fig. 3 (Crawford). Pencil fragments removed via the posterior nares.

Fig. 4 (Crawford). Appearance of patient one week after discharge from hospital.

to be the drug of choice in Friedländer's bacillus infections.[15,16]

Hospitalization began on April 3rd, at which time examination of his left eye revealed moderate proptosis (4 mm. more than the right eye). There was considerably more injection and chemosis, and motion was more restricted. The papilloma had again recurred (figs. 1 and 2). Vision was 20/20, right eye; and 20/30, left. The patient's temperature was normal and his total white-cell count, 9,800.

Since laboratory investigation revealed that the infecting Friedländer organism was extremely sensitive to streptomycin, in spite of the local use of streptomycin ointment, the patient was given 1 gm. of streptomycin intramuscularly daily, divided into 4 doses.

Streptomycin therapy for seven days resulted in considerable, but not complete, clearing. Cultures from the conjunctiva were still positive for Friedländer's bacillus, although the number of colonies was reduced. The nasal cultures were also positive. Blood cultures showed no growth. A rhinolith in the left nares, diagnosed at this time, was thought to be the cause of the persistent infection.

Operation to remove the rhinolith was performed on April 12th. This was found to be the pencil which had been driven through the orbit into the left superoposterior portion of the nasal cavity. Approximately 3½ inches (9 cm.) of pencil fragments were removed through the nose (fig. 3).

Postoperatively, the conjunctiva showed some further clearing and the papilloma was nearly absorbed. Conjunctival cultures be-

came negative for the first time; however, posterior nasal cultures still showed the Friedländer's bacillus, although in much fewer numbers than before.

Penicillin, 40,000 units intramuscularly every 3 hours, was given prophylactically after the operation, in addition to the streptomycin.

Reëxamination of the original X-ray plates showed the pencil, and new plates indicated that about one inch of the pencil remained. It had, apparently, been pulled down into the region of the posterior nares. It was decided that further surgery should not be done at this time, and the patient was discharged to be observed in the clinic. Chemotherapy was discontinued. The patient's total white blood count at this time was 8,560.

The patient returned after one week showing some slight persistent conjunctival injection but the papilloma had been absorbed (fig. 4). During examination he blew out through his nose about a one-inch length of pencil lead. Some wood may still be present. Conjunctival cultures showed no growth; however, nasal cultures showed Friedländer's bacillus, Type A, and coagulase positive Staphylococci albus and aureus.

Two months later the patient had failed to return, although a postcard indicated that he was well.

Conclusion

A case of Friedländer's bacillus infection of the orbit and maxillary sinus following a perforating injury has been reported. The patient was improved after removal of the foreign body and treatment with streptomycin, which is considered to be the drug of choice in Friedländer's bacillus infections.

It is realized that infections with this bacillus may wall off and form abscesses which later may erode through or break down. So far no such tendency has been noticed in this patient.

Also, in conclusion, it must be emphasized that, in a patient with a history of injury, especially with a granulomatous lesion, the possibility of a foreign body should be borne in mind.

ANALYSIS OF OCULAR MOTOR ANOMALIES*

WILLIAM COUNCILMAN OWENS, M.D.
Baltimore, Maryland

One of the most difficult subjects confronting the average house doctor in ophthalmology is the study of ocular motor anomalies. Although he may have a good understanding of the basic anatomy and physiology of the extraocular muscles, he is often confused by the complexity of the clinical findings presented by a patient with strabismus. To find his way successfully through this confusing data, the average house doctor needs an organized method of approach. Only by using such a guide can he readily recognize the important factors in the defect and intelligently institute therapeutic measures to correct them.

THE MOTILITY CLINIC

The first step in organizing the study of motor anomalies in a large hospital is the establishment of a special clinic devoted entirely to studying, classifying, and treating the various forms of motor anomalies. The second step is the use of a simple, practical method of analyzing the complex manifestations presented by patients with ocular motor anomalies.

Two years ago a special clinic for the study and treatment of ocular motor anomalies was started at the Wilmer Institute. The personnel of this clinic includes both ophthalmologists and orthoptic technicians. A member of the teaching staff is in continuous charge of the clinic, and three members of the resident staff, two internes, and one assistant resident are assigned to the clinic in rotation.

Every patient with any type of ocular motor anomaly seen in the general eye dispensary is referred to the Motility Clinic, after a complete external and ophthalmoscopic examination and cycloplegic refraction have been made. The Motility Clinic meets weekly. There the patients are studied by the doctors and orthoptic technicians according to a standardized plan of analysis. When the studies are completed, the patient is presented to the entire group, the problems are discussed, a diagnosis is made, and a plan of therapy is outlined.

If orthoptic training is the first step in therapy, the patient is turned over to the technicians who make subsequent appointments on other days of the week. However, every six weeks the orthoptic technician sends the patient back to the Motility Clinic so that his progress can be observed by the entire group. This provides a constant check on the accuracy of diagnosis and permits any changes necessary in the plan of therapy. If operative treatment is the first therapeutic step, the Motility Clinic recommends the type of operation and follows the patients postoperatively. On discharge from the hospital, an appointment is made for a return visit to the Motility Clinic, where the patient is reëxamined and any further therapeutic measures are instituted.

In this way the Motility Clinic acts as a central clearing house for all patients with motor anomalies. The constant interchange of opinion between the ophthalmologists and the orthoptic technicians has resulted in mutual understanding and excellent coöperation.

We have found this method of joint discussion in a Motility Clinic far better than the former plan of referral of patients to a separate orthoptic clinic. Often doctors referring patients to the orthoptic clinic had little idea of the aims, methods, or problems of the orthoptic technicians. On the other hand, the technicians sometimes lost sight of the broader aspects of the strabismus and in

* From the Wilmer Ophthalmological Institute of The Johns Hopkins Hospital and University. Presented at the sixth annual meeting of the American Association of Orthoptic Technicians, Chicago, Illinois, October 12, 1947.

their intense and persistent efforts to correct some phase of the sensory anomalies, occasionally subjected the patients to unnecessarily prolonged orthoptic treatment. In the Motility Clinic, the members of the house staff become acquainted with the principles and problems of orthoptics and acquire some skill in the use of orthoptic instruments in diagnosis and treatment. By periodic re-examination of the cases by the entire group, it is difficult to overstress any one aspect of the case, and orthoptics is viewed in proper relationship to the other problems of strabismus.

Method of analysis

The tests used in studying motor anomalies should be simple and the method of analyzing the findings should be practical and easily understood. In the Motility Clinic we have found the following plan the most useful one as it enables the house staff and the orthoptic technicians to grasp the significant factors easily. Figure 1 shows the outline of the examination. It occupies a full sheet, which is included in the patient's unit history.

The first topic is a brief history of the patient as related to his motor anomaly. This is followed by a record of his vision, without and with refractive correction. The next topic is the presence or absence of head tilt. The observations on fixation follow. The type of monocular fixation is noted and an evaluation of the angle kappa is made. Under binocular fixation, the fixating eye is determined not only in the primary position for distance and near, but also in the six cardinal directions for near. As pointed out by White[1] and others, these tests are most helpful in selecting the eye upon which to operate. The rotations of the eye are considered next. The extent of the ductions are measured, a screen comitance test is performed, and the relative or absolute near point of convergence noted.

The prism and cover test constitutes the next heading. We have found that this test is extremely useful in giving the house staff and orthoptic technicians a dynamic picture of the motor aspects of the case. However, before the new house doctor is allowed to progress to the prism and cover test he should become adept in performing the tests mentioned above under fixation and rotation. We have found that new members of the staff rapidly acquire skill with the prism and cover test after they have first learned to make careful examinations on fixation and rotation, and have trained themselves always to be conscious of the position of the light reflex on the cornea.

With the prism and cover test, measurements of the angle of squint are made in the primary position for distance and near both with and without glasses. The deviations are also determined for near with the patient fixating in each of the six cardinal directions. The measurement of the angle of deviation in the six cardinal directions has always been an awkward examination to make. Usually there was no way to stabilize the patient's head; an assistant was needed to hold the fixation light, and there was no standardization of the amount of angular rotation of the eyes from the primary position into the six cardinal directions. Because of these difficulties, the house staff and the orthoptic technicians often omitted this part of the examination.

Since the test is so important in analyzing vertical anomalies and in diagnosing incomitance, we constructed a small light to standardize and control fixation in the six cardinal directions.[2] It consists of a base with an upright bar to which is attached a rotating arm. The arm is provided with automatic stops that place it in the six cardinal directions of gaze. Two bulbs in the rotating arm are used for fixation. One bulb, placed at the center of rotation is used for fixation in the primary position at near (33 cm). The other is placed at the end of the rotating arm. When the patient's eyes fixate this peripheral light, their constant angle of rotation from the primary position of gaze is 25 degrees in

each of the six cardinal directions. The instrument is used on a table with an adjustable head and chin rest.

As the patient fixates the central light, the deviation of the eyes in the primary position for near is measured by the prism and cover test. This is followed by similar measurements as the patient fixates the peripheral light successively in each of the six cardinal directions. We have found that this instrument has greatly facilitated the measurement of the deviation by the prism and cover test in the six cardinal directions of gaze.

In performing the prism and cover test it is important to hold the screen a few inches away from the covered eye so that the examiner may look over the screen to observe the movement of the covered eye. The movement of the eye immediately after covering is sometimes easier to follow than the motion of redress on uncovering. It is important, therefore, that the screen should cover the eye only from the object of fixation and not from the observer.

The tests outlined on the chart under the headings of Fixation, Rotation, and Prism and Cover Tests provide most of the information regarding the motor aspects of the case. The remaining portion of the examination is concerned primarily, but not entirely, with the sensory abnormalities. The type of retinal correspondence is determined by the after-image test and the extent of binocular vision is measured with the Worth lights. The major amblyoscope is then used to determine the objective and subjective angle for both distance and near. The type of retinal correspondence is determined; the presence and extent of suppression are defined; the ability to fuse similar pictures is ascertained; and the presence or absence of stereopsis established.

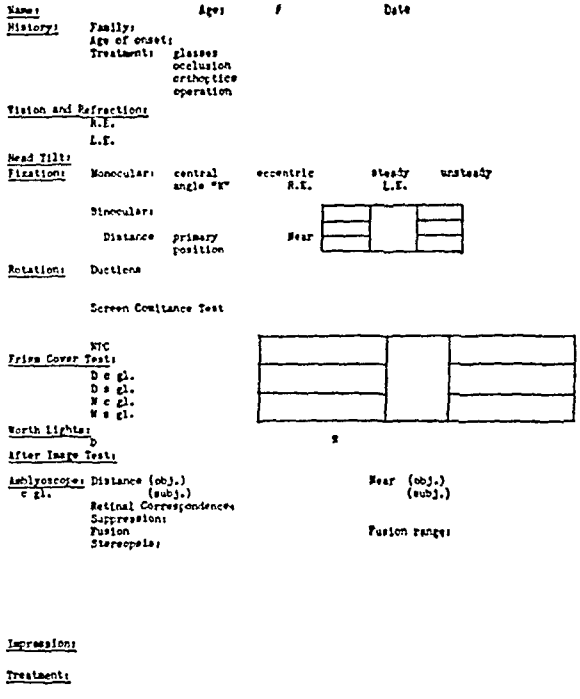

Fig. 1 (Owens). The outline of examination.

We have found that the house staff is generally confused by the classification of fusion into the so-called three grades: simultaneous macular perception, fusion, and stereopsis. They soon find some patients who have the ability to fuse "second grade targets" but lack the ability to superimpose "first grade targets," an ability which is supposed to be a prerequisite for "second grade" fusion.

Burian[3] has pointed out the difficulties in the classification of fusion into three grades. We have found it more satisfactory simply to state the findings in descriptive terms. Any tendency to shift from normal to abnormal correspondence is noted. The presence and severity of suppression are measured by various sized test objects, and the smallest sized target that is not suppressed is recorded. The term fusion is reserved for the ability to integrate similar images produced on corresponding parts of the two retinas into a single mental picture. If fusion is present, the range of convergence and divergence is measured, and finally the presence of stereopsis is determined.

This routine plan of examination is all that is necessary in most of the cases. However, occasionally special tests, such as the head-tilting test described by Bielschowsky, are necessary. The results of these tests can be recorded in the blank space at the bottom of the form.

Evaluation of data

Having obtained this data, the doctor is prepared to evaluate the findings critically and classify the case. Although the same method of analysis is used for all types of motor anomalies, the following discussion will be primarily concerned with cases of convergent strabismus. The horizontal component is considered first. Whether the strabismus is comitant or noncomitant is determined by comparing the squint angle measured in the six cardinal positions of gaze, and coördinating these findings with the results obtained by the tests on ductions and the screen comitance test. This data will separate the paralytic from the nonparalytic squints.

The second point to be considered is whether the strabismus is constant, periodic, or intermittent.

The third factor is to determine whether the squint is alternating or nonalternating. If alternating, the data will tell whether the patient is a true alternator, or whether alternation occurs when fixation is shifted from near to distance vision, or upon shifting the gaze from the left to the right fields of fixation.

From the standpoint of therapy it is important to classify the cases into the accommodative and the nonaccommodative type of strabismus. Patients with the accommodative type have large refractive errors and show a marked decrease in the amount of deviation when the refractive error is corrected. The deviation decreases when fixation is shifted from near to distant objects and often changes from one examination to the next.

Patients with the nonaccommodative type usually have small refractive errors, and exhibit little or no change in the amount of deviation whether the correction is worn or not, or whether fixation is for distant or near objects. In these cases the angle of squint is fairly constant on repeated examinations.

The nonaccommodative type of strabismus is due to two factors. One is mechanical, such as variation in the form of the orbits, the presence of abnormal check ligaments, or faulty insertion of the muscles. The other is excessive innervational tone from a nonaccommodative source.[4] Practically, we find it impossible to separate these two factors preoperatively in most cases or even at operation in some cases of comitant strabismus. Therefore we do not apply the terms mechanical strabismus or tonic strabismus to the cases of comitant nonaccommodative squint since we have no clinical evidence for the separation of the cases into these categories.

The vertical component of the strabismus is considered next. The vertical anomalies are classified as (1) cases due to paralysis of one of the vertical muscles, (2) cases of pseudoparalytic vertical anomalies with overaction of the inferior obliques, (3) cases with comitant vertical deviations, and (4) cases with dissociated innervational vertical anomalies.

The last aspect to be considered is the extent of amblyopia, the type of retinal correspondence, the amount of suppression, and the degree of fusion and stereopsis.

From such a study of the various manifestations of strabismus, the doctors and technicians can arrive at a practical plan of therapy. The cases are divided into those that have a reasonable chance to obtain single binocular vision and those in which only a cosmetic correction of the strabismus is likely to result. In the former, glasses are prescribed to relieve the convergence tone caused by hyperopia, patching is used to overcome amblyopia, and orthoptic treatments are given to overcome anomalous retinal correspondence and suppression. Finally the residual deviation is neutralized by operation. Postoperative orthoptic training is given in all the cases in this group. In general, patients with the accommodative type of strabismus are more likely to obtain single binocular vision and respond to treatment more favorably than patients with the nonaccommodative type. The cases in which only a cosmetic correction of the strabismus is likely to be obtained are sometimes given similar therapeutic measures as a trial. In a few instances we have been surprised to find that some have responded well. Usually, however, surgery is the only therapy of value in these cases.

A standardized method of analysis of ocular motor anomalies is not only of immediate use to the patient, doctor, and orthoptic technician but is also valuable in obtaining uniform records that can be analyzed statistically. One of the present problems in ophthalmology is to gather sufficient data from which to evaluate the various therapeutic measures used in the treatment of ocular motor anomalies. Routine use of a standardized method of analysis will provide information to answer these problems objectively.

Discussion of Dr. Owens's Paper

Frances Walraven
Atlanta, Georgia

Dr. Owens' interesting paper has brought out one of the most vital factors necessary for the successful practice of orthoptics. That is, having an organized method of examining and treating ocular motor anomalies. For successful work a thorough routine examination is essential and should be made of each patient with these abnormalities. This examination should include the information necessary to an analysis from which a correct diagnosis and outline of treatment can be taken.

Present-day orthoptics demand this analysis in order that cases may be classified and that treatment may be directed to the factors involved. After the patient has been classified as to type of case, treatment suited to the individual can be selected. I feel certain that technicians are striving to recognize the different procedures required for each type and individual. To attempt to treat two different types of abnormality in the same manner would not only be unsuccessful but disastrous. When cases are analyzed, such unfortunate experiences do not occur. It is not true that by analysis and direct treatment

every case results in a cure, but a greater percentage of cures can be achieved in this manner. If cures have been accomplished without analyzed and specific treatment we shall certainly have to lay it to luck, or to the fact that we were treating a rare type of case in which almost any kind of treatment could affect a cure.

As Dr. Owens has stated, the method of analysis need not be complicated, but it should be as simple, thorough, and comprehensive as possible. Certainly an analysis of the findings of each case should be made, and periodic consultations between ophthalmologist and technician regarding procedures should be held. With such helpful instruments as Dr. Owens' fixation light, a major amblyoscope, the four-dot test, and like devices, examinations that have been difficult can be made quite easily. Much can be ascertained from these tests both subjectively and objectively.

In analyzing strabismus cases, we have found in our work that a detailed examination and history greatly repay the time required for them. Important indications as to the necessary procedures and the final results depend on information concerning the age at which the squint occurred, duration of the squint, and the age at which the patient is examined. It is desirable to learn if fusion is present, for this knowledge can help to determine whether surgical procedures should be radical or limited. It is well not to depend entirely on motor findings nor entirely on the sensory aspects in determining procedures, as the clinical picture may change with the development and improvement of either one. Age is of importance, especially in very young patients in whom a paresis has shown an almost constant improvement, thereby changing the amount of deviation.

There may be various opinions regarding the grading of binocular vision but the vital factor is to recognize bimacular fixation as necessary to normal retinal correspondence and to develop sufficient fusional range for maintenance of comfortable binocular vision.

In analyzing strabismus cases we divide them into three types for treatment: Accommodative, nonaccommodative, and part accommodative-part nonaccommodative.

Accommodative squints require glasses and orthoptics only for correction.

Squints of a nonaccommodative origin measure practically the same for near and distance. These do not require glasses, but do need surgery and orthoptic training. Among the nonaccommodative types are those squints in which such anatomic factors as faulty insertion of the muscles are involved. These cases seldom respond successfully to orthoptic treatment but depend almost entirely on surgery for correction.

Cases with excessive innervation are classified as part accommodative-part nonaccommodative since the deviation is usually higher for near than distance. A majority need orthoptic training for correction. Refractive errors, if present in these cases, are usually slight. Surgery may be required for the nonaccommodative part, while training similar to accommodative treatment is needed for the excessive innervation even though this factor is not refractive in origin.

Although the various classifications and terms used by different schools have brought about much confusion, a knowledge of the essential differences in each case can direct the orthoptic technician to select the treatment that will give successful results.

Being able to recognize such essential points as the effect, if any, that refraction has on the deviation, what anatomic factors are involved, whether the case belongs in the excessive-innervation group or among the cases of incomitance will contribute toward correct diagnosis and successful treatment.

Continued progress in orthoptics depends to no small extent upon our careful analysis of each individual case in order that we may gather facts with which to further our knowledge and therefore increase the percentage of cures we are able to achieve.

NOTES, CASES, INSTRUMENTS

THE SINISCAL LID PLATE*

A NEW INSTRUMENT

ARTHUR A. SINISCAL, M.D.
Rolla, Missouri

A new type of instrument for retracting the upper (or lower) eyelid during entropion and various other operations is presented herewith (fig. 1). It is hoped that this will fill a long-desired need in the ophthalmologist's armamentarium for a type of instrument that is simple to use and that will keep the eyelid well reflected and open to view for surgical procedure without tearing into the delicate lid tissues and traumatizing them needlessly.

Fig. 1 (Siniscal). The new type of lid plate.

Although particularly adaptable for use in lid surgery, especially for performing the modified Ewing operation for cicatricial entropion,† the instrument may also be used for other surgical procedures with a minimum of trauma to the lid structure and of discomfort to the patient, notably, in the operation for removal of wild hairs in districhiasis, in the surgical removal of imbedded foreign bodies of the conjunctiva (vide infra), and in some plastic operations of the eyelid that require working on the widely exposed conjunctival surfaces, particularly in ptosis operations where shortening of the levator is done (Blascovics).‡

The new instrument (fig. 1) is an outgrowth of the older trachoma lid forceps, used mainly for the removal of the tarsus, which consisted essentially of a flat, round, convex plate on one blade, and of a "biting" or toothed tip on the other end (or blade) of the forceps (fig. 2).

This older instrument was found to be unsatisfactory, since it tore into conjunctival tissue because a good deal of pressure on the closing blade was required to maintain fixation. Furthermore, it did not properly expose the eyelid for retraction because at the point of the "bite" a wrinkling or notching of the lid margin was caused, and this interfered with the path of the knife during incision and also crowded the line of incision at this point (fig. 2).

A later development on this older instrument consisted in neglecting the use of the toothed blade entirely, simply inserting a traction suture at the center of the lid margin, and winding the ends around the forceps post, meanwhile reflecting the lid over the upper toothed blade which was closed and locked.

Further modification was to cut off the toothed blade from the convex blade and simply use the latter, with the screw bind-

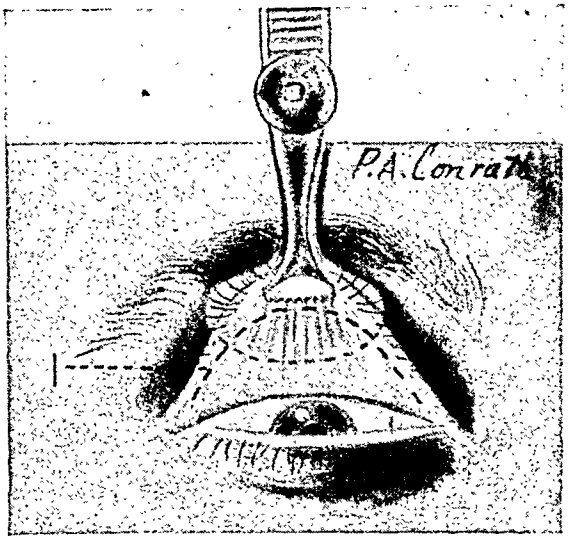

Fig. 2 (Siniscal). Showing old type of lid forceps with biting end tearing into conjunctiva at point of traction. (1) Line of incision for entropion operation. Observe that rounded, convex plate does not afford complete lid counterpressure.

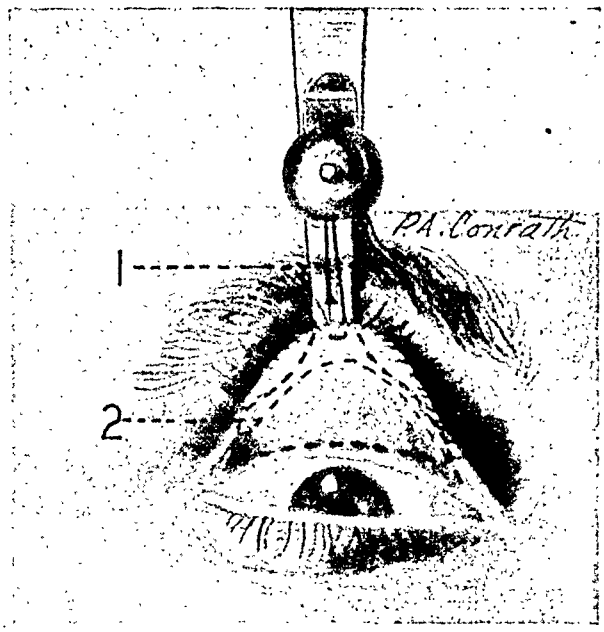

Fig. 3 (Siniscal). Showing new lid plate in use with concave blade extending into corners of reflected eyelid. (1) Traction suture. (2) Line of incision. Observe that new concave plate affords better support by counterpressure for complete line of incision. Concave edge adapts blade to convexity of eyeball.

ing post left intact. This modified instrument was used at the Missouri Trachoma Hospital for many years, with fairly satisfactory results. However, I did not find the convex edge of the lower or supporting blade, or plate, to be best suited for exposing the reflected conjunctiva properly for incision and surgical maneuver.

The new instrument has a larger and somewhat longer plate (or blade), with the presenting edge made *concave* instead of *convex* as in former instruments; the "biting" or toothed end of the forceps has been eliminated entirely so that, instead, a simple tension-spring binding post is used for winding and entwining the ends of the traction suture. As a matter of fact, this instrument is not a forceps at all, since it has only one blade which is an extension of a suitable, weighted handle (fig. 1). It is more correctly called a lid plate.

Figures 3 and 4 show illustrations of the instrument in use, with the upper eyelid reflected well back over the upper surface of the blade or plate, and with a single traction suture inserted through the middle of the lid margin, thus affording a wide exposure of the conjunctival surface when this suture is drawn upward and backward toward the handle of the instrument, and then wound securely around the binding post.

Aside from the simplicity of this new instrument, and its ease of handling, there is an important advantage gained in using a concave-shaped blade, instead of the older, convex-edged type. The latter may afford a fairly good exposure and counterpressure to incision at the broad portion of the lid proper, but it failed short in this purpose at the *corners* of the eyelid.

Here, because of its short, blunt, convex edge the older instrument did not afford sufficient support and retro-exposure for completing the line of incision medially and laterally.

In the new instrument, the elongated concave edge is thus shaped to adapt itself more readily to fit into the retrotarsal fold of the lid (on the dermal side) and because of its wider spread can reach into the corners

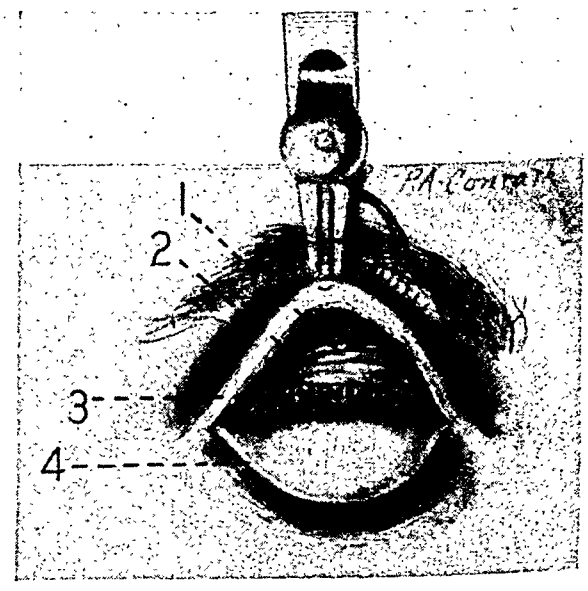

Fig. 4 (Siniscal). Showing new lid plate in use for Blascovics type of ptosis operations. (1) Exposed circular fibers of orbicularis muscle. (2) Detached lid margin. (3) Exposed vertical fibers of levator muscle. (4) Detached portion of conjunctiva and tarsus, stripped from underlying musculature and reflected downward. (Mattress sutures on edge of latter are not shown.)

(angles) of the lid and afford better support by counterpressure when incising the lid at the inner and outer canthal regions.

Furthermore, the newly shaped blade circumvents slipping or "sliding" of the instrument while in use, since its concave edge engages itself aptly into the dermal fold of the reflected eyelid. Slipping and sliding of the older instrument was a fault that frequently caused interruptions and replacement of instrument during operation.

The presence of the spring under the rounded nut on the binding post is to afford tension when the traction suture is entwined (instead of tied) around this post. The nut is turned to the desired tension on the spring, and left in the same position throughout the operation; the traction suture should be wrapped around the post tightly and snugly, and, during the course of the operation—as the need may arise—the suture may be unwound and then reapplied for securing a firmer grip, if so desired.

Although some operators prefer to use three traction sutures during lid operations in place of one, I have found that one suture is usually sufficient for cicatricial entropion operations and for most other procedures requiring repair work on either the upper or lower eyelid. When three sutures are preferred, they may all be wound around the common binding post.

When used on the lower eyelid, the instrument is applied in the same manner, from below, with the blade or plate inserted into the retrotarsal fold and a single, central, traction suture placed through the ciliary margin to retract the eyelid downward over the plate and thus keep it exposed for operative work.

Aside from its use in operations for cicatricial entropion, the new lid plate may also be used for the removal of deeply imbedded foreign bodies located in the inner recesses of the conjunctiva. A small B-B shot was thus removed from the folds of the conjunctiva of a child's lower eyelid. With pressure of the plate applied from the dermal side of the lid, and with widening of the tract of entry on the conjunctival side, the small shot was expressed without difficulty.

Again, during electrolytic epilation operations, it was found that the point of the cautery needle could be more easily directed to the base of the affected cilium when the lid was folded back over such a lid plate and held firmly in place with a traction suture. Since the cilia to be removed are those which have become incurvated or directed toward the cornea, these will appear to stand straight up when the eyelid is retracted, and thus will be more readily accessible.

In another operation, following injury to the eye from a caustic, the lower eyelid was kept well retracted over the new lid plate by a central traction suture; this afforded a wide exposure of the floor of the orbit for the removal of a subtotal symblepharon.

Restoration of the lower sulcus of the orbit was facilitated by retracting the lower eyelid and ciliary margin during the preliminary dissection of the conjunctival flap and insertion of the sutures.

In the Blascovics ptosis operation (fig. 4) the new lid plate will supplant the old type of lid clamp which tears into the ciliary margin from tension during the operation. The new instrument may also be used for tarsectomy and tarsorraphy, or for any procedure for which the older trachoma lid forceps was used. Other applications of the lid plate will suggest themselves to the ophthalmic operator with the subsequent use of this instrument.

Trachoma Hospital.

CHRONIC SIMPLE GLAUCOMA AND THE LABILITY TEST

PETER SYKOWSKI, M.D.
Schenectady, New York

Recently, Bloomfield and Kellerman* reported their results with several tests

* Bloomfield and Kellerman: Am. J. Ophth., 30: 869, (July) 1947.

usually employed for the early detection of chronic simple glaucoma. Prior to this, Bloomfield and Lambert† described fully their method for testing the lability of ocular tension. This method consists in the application, at the same time, of the cold pressor and the jugular compression test. The former investigators reported the apparent superior value of this provocative lability test as a diagnostic procedure.

Results

The convincing soundness of the report prompted the present investigation. This consisted of the use of the lability test in early established cases of chronic simple glaucoma. Thirty-one patients were examined; all 31 gave a positive response according to the criteria described by the authors. The results conclusively corroborated those of the originators.

Comment

The lability test, as a dependable diagnostic procedure, is of unquestionable value. Speaking for it is the factual simplicity of its execution and interpretation, as well as its time-saving element—an item in a busy office.

Although the number of investigated cases was small, all, or 100 percent, showed positive results with the lability test.

The procedure is being recommended as a superior routine provocative test for the detection of early glaucoma.

OPHTHALMIC SMALL BANDAGES*

L. Gát, M.D.
Debrecen, Hungary

It is surprising how little the so-called ophthalmic small bandages are known and still less used. Even in the chapter "Bandages" of the Handbook of Graefe-Saemish, they are not mentioned. Their importance, however, cannot be disputed.

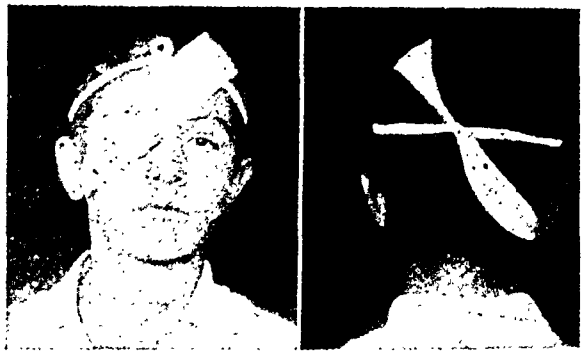

Fig. 1 (Gát). A crossed small bandage.

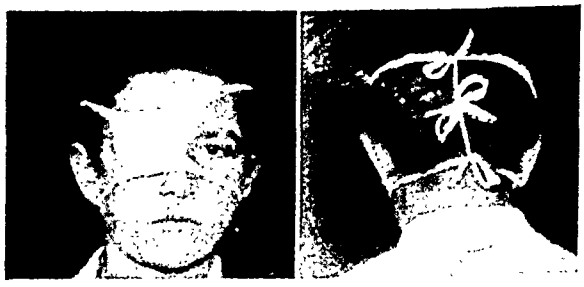

Fig. 2 (Gát). The sling bandage.

The University Eye-Clinik in Debrecen, according to the traditions of the Blaskovics school, used the different kinds of small bandages extensively. Correctly applied they are sure and immovable. A skillfully applied small bandage, with a 80 to 120 cm. swathe, holds more safely and covers better than the monocular bandage used generally.

The most simple is the bandage that we call a "crossed" small bandage because the two branches of the band are crossed over the occiput. First of all, we put gauze and cotton on the eye and then the bandage is applied, its two branches crossed on the occiput and tied on the forehead. It is simple and holds well for 24 hours, even when the patient is bedridden. In general medical practice, this bandage is to be recommended. A strip of material 8 to 10 cm. in breadth and 120 cm. length is enough for this purpose (fig. 1).

The second bandage, more complicated, is the sling bandage. For this a band of 8 to 10 cm. in breadth and 80 cm. in length is

† Bloomfield and Lambert: Arch. Ophth., 34:83, 1945.

* From the University Eye-Clinik, director, Professor Kettesy.

necessary. We split the two ends so that the middle part (8 cm.) remains intact. This middle part is placed on the eye. The split upper band parts are knotted above, the lower ones below the occiput. The two strips are tied together just in the center of occiput, thus avoiding their slipping down (fig. 2). Although, with the crossed small bandage, a displacement can happen or the gauze and cotton may slip down, with the sling bandage, this does not occur.

University Eye Clinic.

REFRACTION CLINIC*

DISCUSSION BY

ALBERT E. SLOANE, M.D.†
Boston, Massachusetts

These two cases deal with keeping people relatively happy with old glasses, rather than in making people unhappy with new glasses. This is a negative approach rather than a positive one. A lesson may be learned in the practical management of such cases.

CASE 1

The first patient is a woman who is 79 years of age, and she has not had her glasses checked in 25 years. Her right eye was lost at the age of four years from "scarlet fever," and other than for some early lens changes, the left eye was normal.

She was wearing: O.D., balance lens; O.S., −0.75D. sph. ⊂ −1.25D. cyl. ax. 55° = 20/100+; addition, +2.00.

She was refracted with considerable care because we noticed that she was able to get with a subjective examination: O.D., anophthalmus; O.S., 20/200; with a −1.50D. sph. ⊂ −1.25D. cyl. ax. 80° = 20/40 slowly; addition, +2.50. Pinhole does not improve further. So, these glasses were prescribed, and the doctor assured the patient that she would be happy because, with her new glasses, she should be able to see better.

One month later, the lady returned complaining that she was having bifocal trouble which she did not have before. "The segment was a little bit higher than in her own lens," and it "kept getting in her way." The glasses were checked for power, and the refraction rechecked. Both were found to be correct, and the patient was referred to the optician for adjustment of her glasses.

She was again seen with multiple complaints referable both to conjunctival irritation and her new glasses. She was given some collyrium for the conjunctivitis, and again reassured about her glasses.

And three weeks later, she again returned with many complaints attributable to her glasses. Again refraction was rechecked. The glasses were found to be correct.

DISCUSSION

In general, it may be said that if a person wears her glasses for a long period of time, she will be more resistant to any sort of a change made. One, then, has to weigh whether the added visual benefits will offset the required various new adjustments, such as judgment of distance, new frames, and new strong lenses.

If the patient's symptoms are not specifically and entirely tied up with the need for a change in glasses, it is frequently better to make no change at all. Sometimes, even three lines of vision are better sacrificed than to reintroduce the patient to the new adjustments which different glasses make necessary.

In this particular case, where the patient wore her present glasses for 25 years, we have such a situation. Another factor in this case resolves itself about the fact that she has been able to wear her glasses for this period of time. This is probably due to two factors:

First, she was wearing 0.75 diopters less myopic correction than she requires. This would serve to give her a comfortable work-

---

*From the House Officers' Teaching Clinic, Massachusetts Eye and Ear Infirmary.

† Director of Department of Refraction.

ing near range through her distant glasses for most of her occupations; for example, eating, washing dishes, and so forth.

Secondly, this undercorrection would tend to express itself in the form of a stronger presbyopic correction for near; thus 0.75 diopters of uncorrected myopia would tend to increase her near vision. Since the reduction of vision in such cases is very gradual, she may not have noted or missed that her distant vision was particularly failing. And also, her needs for greater distant vision is not as great as in a person who leads an active, outdoor life.

I do not mean to infer that one should never change glasses in old people. But if you are in doubt, you frequently get into less difficulty if you do not change the glasses. Since the patient could not make the necessary adjustment, her old lens was reinserted. She was told to keep her new lenses for possible future use. Sometimes, a person who resists a new glass in favor of her old glass, finds that when the old lens is again used, it doesn't equal the new glass in its suitability, and then the patient is more willing to go back to the new one. The point I might make in regard to that is "Always try to have the patient keep her old glasses if you make a change." Because, if she has difficulty with the new lenses, she will soon learn by comparison that her old lenses were not as good as she thought they were.

Case 2

The second patient in this group is a woman, aged 70 years. She has been wearing her present glasses for 15 years: O.D. +0.25D. sph.. ⊃ −1.0D. cyl. ax. 10°; O.S., +0.25D. sph. ⊃ −1.0D. cyl. ax. 165°; addition, +2.50.

We have no record of how much vision she had with her old glasses, but a subjective examination revealed the following: O.D., +0.25D. sph. ⊃ −1.25D. cyl. ax. 20° = 20/20; O.S., +0.75D. sph. ⊃ −1.5D. cyl. ax. 140° = 20/20; addition, +3.0. And, she could read the finest print. The glasses were changed.

Four months later, she came into the hospital complaining that she was unable to wear her new glasses because of the discomfort they produced, and that she finds considerable relief when she puts on her old glasses. The examination of her eyes, other than for retinal arteriosclerosis, was not remarkable. The glasses were rechecked, and it was found that with them, she had 20/20 vision.

The refraction proved correct, but a note was made that the interpupillary distance of the new frames was considerably greater than that of the old ones. So, she was referred to the optician to correct the situation.

Two months later, she again returned, insisting on having her money back. She was unhappy with her glasses, and had fixed ideas about their strength, and the note at the bottom of the record read, "Everybody would be happier if the glasses had not been changed." Here, again, we have a person who has worn her glasses too long, who is too set in her habits, and at home, even though the visual acuity was improved, found it difficult to adjust herself to the new glasses.

Discussion

It is just as well to explain that, when a person reaches the arteriosclerotic age, they do not learn new tricks easily. If no harm is done by not changing the status quo too much, no treatment may be as good a treatment as any. You prescribe a little zinc, and let the next fellow change the glasses.

Questions

House Officer: Is it not true that these people may have had difficulty with their eyes that led them to have the prescription for their eyes checked?

Dr. Sloane: I am told that, in both cases, the patients admitted that they were told that it was advisable to change their glasses after such a long period of time.

House Officer: How long a period of time does one have to wear glasses before they reach this "resistant-to-change state?"

Dr. Sloane: I would say 10 years or more would make me wary.

House Officer: In Case 1, if 20/100 vision is considered a serious blurred state, wouldn't it be better to improve her distant vision some?

Dr. Sloane: Perhaps, half way, such as giving her −1.12 instead of −1.50.

House Officer: In view of the difference in the first case of the sphere and in the axis of cylinder, would you not attempt ordinarily to correct this patient, and take your chances that the patient would be happy?

Dr. Sloane: Everybody is clever in reasoning post hoc. I probably would have tried to evaluate her symptoms in terms of "need for change of glasses," and if the symptoms were not visual, I probably would not have changed her glasses.

As far as axis of cylinder is concerned, by wearing her cylinder at the wrong axis, an artificially produced oblique astigmatism was present for which she had had an adequate number of years to make allowances, and, if you change the axis to the correct position, you may be introducing a new criterion of judgment to which she must adjust.

Frequently, you will have a person who has a strong cylinder, for example, at axis 105°, and they have never worn glasses before. They never complain without glasses that vertical lines are tipped, because they interpret this position as the normal straight position. When you give them the correct glass, one of the first symptoms they complain of is, "that everything that is straight is now tipped," and they must make an adjustment to this until it corrects itself.

There is another point on the old lady. A cylinder that is not at the correct axis in a younger person may induce an accommodative effort in order to correct the blur, and this accommodative effort will produce fatigue. The wrong axis will make for eyes blurring. In a person of this age without any accommodation, no effort is made to correct this blurring, so that she has the blur without the fatigue.

House Officer: Assume that you had prescribed the above glasses, how long would you insist that the patient try to become adjusted?

Dr. Sloane: Since some patients can adjust themselves, one should insist as long as they honestly believe that they are gaining ground. You can easily determine by talking to the patient whether they are ever going to get used to them at all. I believe it is fair to say to the patient that it is to her advantage to get used to the new glasses, because that in itself may be the incentive that will make it possible.

ETIOLOGY AND THERAPY OF ACUTE RETROBULBAR NEURITIS*

Lo Wen-Bin, M.D.
Chengtu, Szechuan, China

Acute retrobulbar neuritis is not a rare disease in China and we have had here about nine cases a year at this hospital. It is difficult to get a clear opinion about the frequency of acute retrobulbar neuritis; it may be that this disease alarms the patients and induces them to go earlier to the hospital than patients with other diseases, who come as a rule very late to see a doctor, often waiting for months. The frequency of retrobulbar neuritis is especially striking as in China we have apparently no multiple sclerosis, which occurs frequently in Europe. The etiology of retrobulbar neuritis in China is especially obscure. The rhinologic factor, causing an inflammation of the optic nerve is not usually found. Rhinologic therapy—such as the application of a swab

* From the Eye, Ear, Nose and Throat Hospital.

soaked in adrenalin or cocaine, scarification of the concha or opening of the ethmoid cells—does not, as a rule, bring any relief. According to Ernst Fuchs, acute retrobulbar neuritis frequently shows the same type of inflammation of the nerve as the neuritis of the nervus facialis or abducens or sciaticus. These cases were formerly called, and probably rightly so, rheumatic inflammations.

Although there is no multiple sclerosis in China, there are cases of recurring acute retrobulbar neuritis as, for instance, that of a patient, aged 25 years, who had retrobulbar neuritis in the right eye and, later, temporal pallor with normal vision. Recently, he has suffered from severe retrobulbar neuritis of the left eye. A similar case of recurrent retrobulbar neuritis was seen lately by Prof. Adalbert Fuchs in Nanking.

Report of a case

A colonel, aged 38 years, had severe acute retrobulbar neuritis 10 years ago in both eyes. The left eye had become affected a month after the right. His vision at that time was 6/60. He recovered without treatment in seven months and his vision became 6/6. In August, 1946, his vision in the right eye dropped in one day from 6/6 to hand movements. The eye was tender to touch but there was no pain on motion. A week later the left eye also became involved, and he could only count fingers.

A careful general examination did not reveal any etiology and search for evidence of multiple sclerosis was absolutely in vain. In September, he was given penicillin and he became able to read J8. In October, the tonsils were removed and the ethmoids opened. Four days after the operation the vision improved somewhat and he saw, with the right eye J5, and with the left eye, J2. Later on the vision improved a little and in May, 1947, his vision was: 6/8, J1, O.U. The right papilla was a little pale on the temporal side, the left normal.

Although this case improved somewhat after the operation on the nose, it is not certain that it was really caused by an empyema or chronic inflammation of the ethmoidal cells, especially as nothing was mentioned of any local change or of any secretion.

Therapy of retrobulbar neuritis

The therapy of retrobulbar neuritis is somewhat different in China from that used in Europe. We cannot use diaphoresis which proves so valuable in other countries. This is due to different causes: (1) The Chinese do not like to perspire. (2) It is difficult to make them perspire. (3) The facilities for inducing perspiration, such as bathrooms, steambaths, heat boxes, lightbaths, and so forth are lacking in most places in China.

Because of these mentioned contraindications, typhoid vaccine has been chiefly favored throughout this country as a form of fever therapy; an initial dose of 5,000,000 bacilli is injected intravenously with a subsequent increase of 50 percent in dosage. The fever occasionally rises to 39°C. and often reaches only 37.5°C.

Milk injections are rarely used in China, apparently because the Chinese react very little to milk, even after 10 cc. have been injected intramuscularly. The cause of this resistance is perhaps the fact that the milk is not a mixed milk as in Europe and comes mostly from one cow and is boiled immediately so that no germs can proliferate in the milk. Injections of 5 to 8 cc. of condensed milk prove very useful, however, if taken directly out of the tin without further boiling. Condensed milk is easily available even in small places in China. These injections give a strong fever reaction with considerable certainty.

Acute form of disease

We recently had a very severe case of acute retrobulbar neuritis of unusual appearance in which the therapy had a striking result.

Case report. A Chinese woman, 51 years

of age, felt slight visual disturbance in the right eye six days before examination. Her vision dropped in three days to hand movements at 30 cm. She was admitted to our hospital. At that time she had slight pain on moving or by touching the eye. The papilla showed a typical choked disc with hyperemia, blurred margin, engorged veins, small hemorrhages, and a mushroom-shaped elevation of three diopters. The left eye was normal. Vision was: O.S., with a +1.0D. sph., 6/6.

On the next day only light perception was noted. On the second day after admission she was given 5 cc. of milk intramuscularly. The day following both light perception and light reflex of the pupil had vanished. An injection of 10 cc. of milk was made on the fifth day and produced a high temperature but no improvement in vision. Two days later 5 cc. yatren-casein was injected intramuscularly. The light sensation and light reflex of the pupil had not been present for three days. The disc showed an increased amount of hemorrhages. This was perceived on the seventh day after admission. Three days later, another 5-cc. dose of yatren-casein was given.

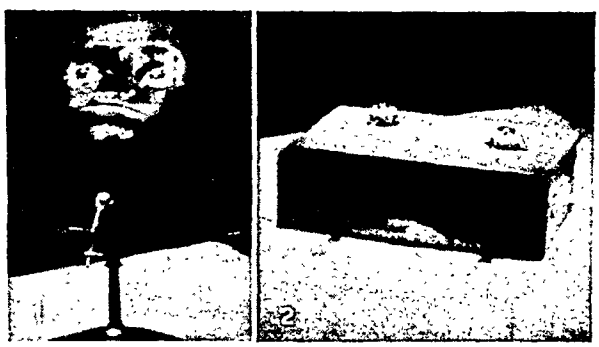
On the 12th day after admission, light perception reappeared, after not having been present 7 days. This was 4 days after the first injection of yatren-casein. She could count fingers on the temporal side at 12 cm. On the 14th and 16th days, another yatren-casein injection (5 cc.) was given. After this she could count fingers at 20 cm.; while standing at 6 meters she could see movements of the leg in the inferior part. From the 19th to the 38th day after admission, she was given 1 cc. of yatren-casein every day. Vision improved slowly. On the 29th day, a central scotoma could be found with the perimeter. The outline of the papilla became gradually distinct and the swelling disappeared. She was discharged on the 38th day after admission. The vision of the right eye was 6/15 and the papilla appeared normal, except that in the neighborhood of the disc there were a few small superficial hemorrhages. Two weeks later vision was 5/10.

Discussion

This case differs from the cases of Dr. Fuchs in its clinical appearance. The disc was not normal but appeared like a very badly choked disc with high elevation and many hemorrhages. Acute retrobulbar neuritis sometimes shows a marked papillitis, but such a highly choked disc is rare. That was the reason we did not make the correct diagnosis at first. We searched for a brain tumor, but the absence of headache, vertigo, and vomiting made a brain tumor very unlikely. Tenderness of the eye led us to the final diagnosis.

2. Against a diagnosis of choked disc in the common sense spoke the development of perfect blindness and absence of light sensation, which never develops so quickly in a common choked disc due to the increase of intracranial pressure. The patient did not become blind as quickly as the cases of Dr. Fuchs.

3. The milk injections did not show any change of the vision but the use of high doses of yatren-casein forte, which was given us by Professor Fuchs, produced an improvement of vision, light sensation appeared and pupillary reaction was visible when the light was directed from the temporal side. The improvement was slow at first and became more rapid. Finally when the vision had reached 6/12 we stopped the injections because the medicine had run out.



Intramuscular injections of yatren-casein are usually given in small doses (1 cc.) intramuscularly. Even cases which are quite resistant to ordinary therapy and come rather late, react very well to this therapy.

Eye, Ear, Nose, and Throat Hospital.

A PHANTOM FOR ANIMAL EYE SURGERY*

ALFRED A. STONEHILL, M.B.
Chicago, Illinois

Figures 1 and 2 represent eye phantoms in common usage for training in pig-eye and cat-eye surgery. The first (fig. 1) is a modification of the Vienna mask which operates by grasping the optic nerve of the eye. A screw arrangement draws the eye into a conical wire basket and also permits the tension to be varied. The second (fig. 2) was designed by the late W. A. Fisher.† In this

Figs. 1 and 2 (Stonehill). (1) Modification of the Vienna mask which operates by grasping the optic nerve of the eye. (2) Designed by Fisher, this type of phantom uses a suture to hold the eye in position.

phantom, a suture is placed through the optic nerve, and the thread is passed through a hole in a cigar box and attached to a wooden rod which protrudes through both sides. As the rod is rotated, the suture is tightened and the eye is held in position.

In our experience the mechanical-type phantom is cumbersome to adjust and requires considerable time to insert material. The eye is not held tightly, nor can it be placed in any desired position. Securing eyes in the Fisher phantom is also a laborious and time-consuming procedure. The human face is not simulated and the eye is unsteady and difficult to fix.

Figure 3 shows a phantom in which the holding device is a vacuum cup. To this is attached a short piece of rubber tubing and a soft rubber bulb. The bulb is squeezed; the eye is inserted in the cup in any desired position and held in place by negative pressure when the bulb is released. The eye is quickly removed by pressing the bulb which still contains sufficient residual air to force the eye out of the cup. A small wire guard prevents the eye from entering too deeply into the cup.

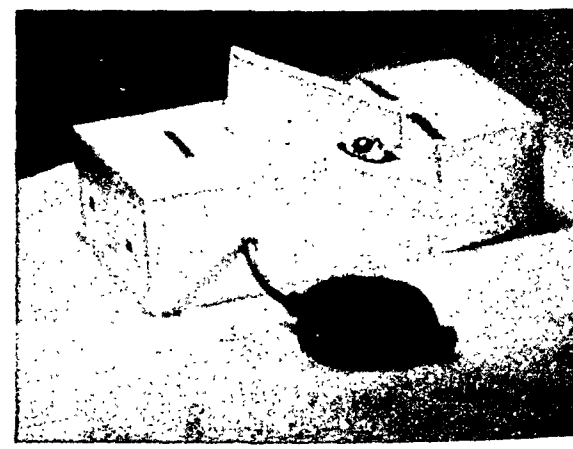


Fig. 3 (Stonehill). The holding device in this phantom is a vacuum cup.

The face consists of a cigar box modified to exaggerate facial contours. A deep orbit is simulated and the obstruction of the forehead and nose is present. These are constructed from cardboard.

The rubber cup is a crutch tip (size 19) and is available in many sizes. To it is attached a short piece of rubber tubing, using a metal connector or rubber cement. The rubber bulb is standard, but valves must be removed and the inlet hole closed with an appropriate plug. These can be obtained from a penicillin or vaccine bottle and cemented in place.

SOCIETY PROCEEDINGS

Edited by DONALD J. LYLE, M.D.

NEW YORK SOCIETY FOR CLINICAL OPHTHALMOLOGY

November 3, 1947

DR. DANIEL KRAVITZ, *president*

SYSTEMATIC EXAMINATION OF THE EYE

DR. HENRY J. MINSKY discussed this subject during the instruction period.

SOME UNSOLVED PROBLEMS IN SQUINT

DR. FRANCIS HEED ADLER first discussed whether comitance rules out paralysis of a muscle in cases of squint. He said that frank incomitance in the angle of squint is generally regarded as a sure indication that the strabismus is either paralytic or due to an anatomic abnormality, such as faulty insertion of a muscle. The one exception to this is the elevation of an eye in adduction which occurs in some otherwise comitant squints, and which is regarded by most authors as representing the normal preponderance of the inferior oblique over that of the superior oblique. This preponderance is due, according to their point of view, to the fact that the inferior oblique is a longer muscle and has a longer arc of contact.

In considering the question, of whether comitance rules out a paralysis, he said that many authors agree that a squint which was incomitant at its beginning may, with the passage of time, become comitant due to either spasm or contracture of the direct antagonist or of the yoke muscle of the paretic muscle. When the paretic muscle recovers from its paralysis, the comitant element remains.

Dr. Adler said that there is very little proof that this is true. It is of more than academic interest to determine whether it is true or not in that it determines our decision as to the nature of the strabismus in any case; that is, whether the squint is paralytic or innervational and this should considerably alter the prognosis and type of treatment.

Contracture of a muscle may undoubtedly occur in severe paralysis and lead to a comitant element in a squint. In such cases, however, the angle of squint still remains incomitant due to overaction of the yoke muscle. A muscle which was paralyzed may regain sufficient power to move the eye completely in the direction of its action, but as long as any weakness remains this will be manifest by the overaction of the yoke muscle, based on Hering's law.

Dr. Adler said that he had never seen a case of paralysis of an ocular muscle occurring in an adult become comitant. There may develop a strabismus in the primary position of gaze, due to contracture of the antagonist muscle; namely, the internal rectus in a case of external rectus palsy, but the squint is still incomitant, even in partial recovery of the externus, due to overaction of the internal rectus in the opposite eye. This is always a sign of paralysis of a muscle.

No one has examined muscles which are thought to be contractured to determine whether or not they are fibrosed. Further the term "spasm" when applied to a muscle is purely hypothetical. Studies should be made to determine the basis of what contracture of a muscle is, and if possible physiologic evidence should be produced to show that a muscle termed "spastic" is really undergoing spasm. Any paper or book in which such terms are used freely should be examined with caution.

Dr. Adler next discussed the question of whether a horizontal strabismus can arise from a paralysis of a vertical muscle. He said that it seems reasonable to suppose that a paralysis of a vertically acting muscle could dissociate the eyes in the same manner as

inserting vertical prisms before one eye changes an existing horizontal phoria to a tropia. Once the dissociation has become manifest and continued for any period of time it might become permanent. An additional component of the strabismus should be comitant while there should always be elicited some evidence of incomitance.

Dr. Adler then spoke of the meaning of anomalous correspondence. He said that there are two fundamental concepts regarding retinal correspondence. (1) That it is innate, and (2) that it is acquired. The vast majority consider it acquired and that anomalous correspondence arises out of squint, perhaps as an adaptation to the angle of squint. It is a poor adaptation, if this is so, since it could only be effective in normal life in those cases of harmonious correspondence where the subjective and objective angles are equal. In most cases of squint with so-called anomalous correspondence, there is no correspondence. Due to suppression, the region of the retina where the image customarily falls is suppressed and no spot in that retina has the same locus in space as the macula of the fixing eye. It is true that, by training, anomalous correspondence may be broken up and normal correspondence established in many cases.

Dr. Adler then asked whether anomalous correspondence could develop in a case that had normal correspondence. He said that it is possible that anomalous correspondence is innate and due perhaps to some anatomic defect in the arrangement of the visual pathways. From this point of view it might even be considered the cause of squint in large-angle squints. In an analysis of our series, we found that the large majority of squints under 15 degrees had normal correspondence, while over 15 degrees they had anomalous correspondence. A sudden break came at this point. It is possible that the region of the retina beyond the optic disc on the nasal side contains fibers which yield anomalous correspondence, while those between the disc and macula yield normal correspondence.

Principles of ocular muscle surgery

Dr. Rudolph Aebli stated that there are three principles in the surgery of extraocular muscles: (1) To weaken a strong muscle or function, (2) to strengthen a weak muscle or function, (3) to confine all surgery to the particular field or fields involved, and not to disturb those fields of action in which the muscle balance is relatively normal.

Generally speaking, he said, it is good policy not to cripple the function of any one muscle excessively but to spread the operation over multiple muscles; for each millimeter of recession one figures to correct 4 to 5 prism diopters. These results vary and are flexible but are a basis for preoperative calculations of the muscles operated. Thus deviations of 20 to 25 degrees can be corrected by operating one muscle, deviations of 40 to 50 degrees are best corrected by operating on two muscles, and deviations of 70 degrees or more should be corrected by operating on three or more muscles. By adhering to these rules no one muscle is excessively crippled and the movements of convergence and divergence and associated lateral movements are well maintained.

Recession of the inferior oblique of about 10 mm. corrects about 20 degrees of hyperphoria in the primary position, and has replaced myectomy at the origin, as the results can be gauged more accurately.

The fixating eye in the primary position and in the six cardinal fields is important and operative procedures should be varied, depending on the choice of fixation. Thus in nonparalytic convergent strabismus where the right eye fixates in the primary position and in eyes right, and the left eye fixates occasionally in the primary position but constantly in eyes left, there is no limitation of outward rotation of either eye but there is generally a marked inward rotation of the

nonfixing eye. In such cases surgical measures applied to the rectus interni to stop the overaction produce very favorable results. In cases of double elevator paralysis of one eye in which fixation is constantly with the sound eye, it is better to raise the lower eye; in those that fixate with the paretic eye, it is better to lower the higher eye; in those that alternate fixation, it is good policy to divide the operation between the two eyes.

A few remarks on technique are in order. It is advisable not to disturb the normal anatomic relationships and to maintain the fascial muscle envelopes. The sutures hold better and less hemorrhage is encountered. Retraction of the caruncle must be avoided and the supporting structures should not be disturbed. Scleral fixation is not foolproof, and clots and raw surfaces tend to produce adhesions to the underlying sclera with disappointing results.

Dr. Aebli concluded his discussion with slides and case reports illustrating the principles he had discussed and showing errors in technique and in operative judgement.

Diagnostic criteria in surgical management of lateral deviations

Dr. Harold W. Brown emphasized the surgical importance of an accurate diagnosis. He said that if the accommodative convergence and the divergence functions are considered as direct antagonists, the comitant convergent squints can be classified as primary convergence excess, or divergence insufficiency and the relationship or amount of the secondary over- or underaction of the antagonistic function will serve as a surgical guide, as to which functions (convergence or divergence) should be strengthened or weakened. The divergent comitant deviations are classified in the same manner.

Dr. Brown discussed the question of whether the deviation is primarily a divergence excess or a convergence insufficiency. He said that the determination of the amount of secondary overaction of the divergence in convergence insufficiency and the amount of secondary underaction of convergence in the primary divergence excess type, will be the determining factor as to the amount of recession of the externi, or the amount of resection of the interni that should be done to correct the divergent lateral deviation.

In the noncomitant or paralytic lateral deviations, the diagnosis of the paretic muscle is usually evident by the failure of the muscle to rotate the eye fully in its field of action. The cause of this failure may be due to a primary weakness of the nerve, congenital anomaly of the insertion, structural change in the muscle, or limitating fibrous bands in the direct antagonist.

A nerve or muscle weakness will usually show a secondary contracture of the direct antagonist or secondary deviation of its associate muscle in the other eye, or both. Surgery of a truly paralytic type is based on a strengthening operation of the paralytic muscle or a weakening operation of the direct antagonist or the yoke muscle of the other eye.

In those cases where the restricted action is due to a limiting fibrous band in the direct antagonist, such as is found in retraction syndromes, there is usually no secondary contractures or deviations, and the surgical management will depend on the functional integrity of both the muscle involved and its direct antagonist. The range of movement is usually limited and surgery should be confined to shifting that range nearer the primary position.

Lateral squints that show a vertical deviation will call for a careful analysis of the lateral deviations, in terms of both the over and underactions of the disjunctive functions of convergence and divergence, by measuring the deviation of distance and near, and in the six cardinal fields of gaze, for the over- and underactions of the individual muscles. After the diagnosis is made, the surgical correction of the greatest devia-

tion, either the vertical or lateral, and the field where that deviation increases, seems to be the safest surgical procedure.

The variations and combinations of the dysfunctions of convergence, divergence, individual anomalies and their secondary deviations and contractures, and the complicating vertical deviations defy any final standardization of the surgical management of these lateral deviations, based on anything other than a diagnostic analysis of each individual case.

Discussion. Dr. James W. Smith said that Dr. Adler had brought some new and stimulating thoughts on ophthalmic physiology. He said that one becomes confused by authors who use the same words with different meanings. He mentioned the use of such terms as muscle overaction, underaction, spasm, contraction, overshoot, paresis, palsy, partial paralysis, and paralysis. To this array, Bielschowsky has added congenital overaction of the inferior oblique muscle; another contribution made by Chavasse (and stressed by Dr. Adler in a recent paper) is inhibited palsy of the contralateral antagonist. Dr. Adler once again made an appeal for uniformity in eye-muscle terminology.

Dr. Smith said that we diagnose, treat, and operate too late in life to achieve binocular single vision. He stressed the need to educate the general practitioner, pediatrician, and some ophthalmologists to the importance of bringing patients for treatment in infancy and early childhood if amblyopia is to be forestalled. Many patients, who recognize deviations early in childhood, have been dissuaded by their medical advisers from seeking ophthalmic treatment immediately. Most of the cases can then only be improved cosmetically. Only a few are brought for observation early enough to effect recovery of binocular single vision.

Dr. Edwin B. Dunphy, *presiding*

Tumors of the orbit

Dr. Arnold Forrest of New York reported an analysis of 204 cases of intraorbital tumor in the files of the Registry of Ophthalmic Pathology. It was noted that, of the 168 primary tumors, there were 89 masses of mesenchymal origin including those related to connective tissue, to the vascular tree, and to the hematopoietic system. Fifteen mixed tumors had arisen in lacrimal gland. Forty-eight neoplasms were of neurogenous origin and included those arising in peripheral nerve sheaths, meninges, and optic nerve. Eighteen dermoids were noted. In 42 instances of primary intraorbital neoplasm, the tumor was malignant; one third of these patients had a five-year cure. In addition, 24 carcinomas, 6 neuroblastomas, 5 melanomas, and 1 pituitary melanoma noted in the orbit had arisen in a primary site elsewhere.

In the discussion that followed, Dr. Frederick Verhoeff noted that the cylindroma, lymphangioma, and liposarcoma were not included in the classified types.

Dr. Forrest replied that the cylindromas were included in the mixed tumors, and that the specific tumors in the Registry to which Dr. Verhoeff referred as lymphangioma and liposarcoma were placed in the groups of angioma and undifferentiated sarcoma, respectively, since there had not been universal agreement among the pathologists on the question of their differentiation.

Dr. Parker Heath said that it was only by such a series of cases as Dr. Forrest presented and other series that other laboratories are trying to produce that one can really arrive at some sort of good surgical judgement in the management of these cases.

OCULAR HYPOTONY

DR. PARKER HEATH of Boston presented this subject which he defined as: intraocular pressure below the normal for that eye. An arbitrary upper limit is 10 mm. Hg (Schiøtz) or the equivalent. Low pressure is often associated with deterioration of the globe.

Facts and theories relating to cause were discussed with the following headings: contusions, nervous origin, perforating wound and injury, myopia, uveitis, detachment of retina, congenital malformation, general disease states, endocrine imbalance, drug and surgical therapy, and spontaneous causes.

The pathology of hypotony related to severity and duration. Occasional signs are edema of lid; enophthalmos; cornea thickening; wrinkles of cornea; radius of curvature lessens; edema of epithelium; iris congested, cystic at times, pigment movement; anterior chamber deepened; iris angle more right angled; angle trabeculum looser; diameters increased; aqueous plasmoid and contains cells; ciliary body atrophic or inflammed; cyclitic lens change common; scelra thickened; vitreous and aqueous more xanthotic; suprachoroidal space enlarged by fluid; choroid congested or disorganized; retina cystic—pigment migration; detachment often; nervehead edematous, sometimes choked. Clinical significances were discussed.

Dr. Frederick Verhoeff opened the discussion of the paper. He mentioned the hypotony that occurs in eyes with subsiding infection. The eye may have good light projection, so that one hesitates to take the eye out. He had never observed the tension in such eyes to become normal, and he asked Dr. Heath if he knew how to raise the tension in such cases.

Dr. Verhoeff took issue with Dr. Heath, who, he said, apparently agreed with Dr. O'Brien in regard to the great frequency of separation of the choroid 24 hours after the operation. He felt that the appearance is due to indentation of the sclera, since the eye is examined when it is still soft. He personally did not believe separation of the choroid occurs in every case. However, he felt that one does get a separation quite often when there is prolonged low tension. He noted that it was Barkan who first thought the separation of the choroid was due to leak of aqueous through the wound.

In cases in which the choroid did not go back in a reasonable time, he thought a scleral puncture should be done. He mentioned two cases of spontaneous separation of the choroid, one in a low-tension eye. In one case the retina was not separated, the fluid behind the choroid contained very little serum, the patient had had diarrhea for years. In the other case there was also some separation of the retina.

Dr. Verhoeff observed that several cases of choroidal separation have been associated with hypertension with nephritis, which caused trouble in the choroid. He felt that the fact that separation of the choroid does not occur more commonly is proof that aqueous is a secretion, not a transudate, for by simple transudation the fluid could go more easily into the ciliary body, thence to the subchoroidal space, than through the membranes, and so forth to the aqueous.

Dr. William Beetham pointed out that in diabetics studied by Dr. Waite and himself only the ones in coma and with true glaucomas showed demonstrable variations in tension. He thought that an iridencleisis was the operation of choice in chronic glaucoma, especially in older people, since hypotony may develop with the trephining operation.

Dr. Paul Chandler pointed out that in those cases of contused globe with reduced vision, the reduction is due to a refractive error, usually a high astigmatism from pressure of the lids on the cornea. A chalazion of the upper lid may cause pressure on the globe sufficient to cause astigmatism of considerable degree if the intraocular pressure is 15 mm. Hg (Schiøtz) or less.

Dr. Judd Beach asked which comes first,

the hypotony or the uveitis. Dr. Cogan inquired as to where the vitreous goes if there is a separation of the choroid.

Dr. Heath in reply said that myopia was present in one third of the cases with hypotony. In detachment of the retina there may be noted marked reduction in caliber of the blood vessels of the retina. He has the impression from laboratory material that the fluid outside the choroid is transient, while the fluid under a separated retina is more permanent. In reply to Dr. Beach, he thought the uveitis usually came first. In regard to where the vitreous goes, he said the vitreous was mostly water, and this may be resorbed and later replaced by more water, by some process not fully known at present.

Dr. Burton Chance, *chairman*

Mixed-cell tumor of lacrimal gland

Dr. I. Edward Rubin (by invitation) presented a follow up on a case of mixed cell tumor of the lacrimal gland which was presented to this society one year ago.

Case Report. F. Y., a 36-year-old white man, developed a tumor of the left lacrimal gland at the age of 10 years. The tumor was excised when he was 16 years of age and was reported to be a "mixed tumor" of the lacrimal gland. It recurred 11 years later, when the patient was aged 27 years, and failed to respond to a full course of X-ray therapy. A retrobulbar tumor mass was removed from the left orbit of the patient now aged 33 years. Again, the pathologic report was "mixed tumor" of the lacrimal gland.

The tumor soon recurred, producing complete ptosis of the left upper lid and a moderate proptosis. In March, 1946 (age now 35 years), papilledema of the left nervehead was first noted and an intracranial extension of the tumor was feared.

In July, 1946, at the Graduate Hospital, Dr. Robert Groff performed a left frontoparietal craniotomy and found no intracranial extension; but the left orbit was filled with tumor tissue which compressed the left optic nerve. Dr. Groff removed most of the tumor. The pathologic report was adenocarcinoma.

Two weeks later in August, 1946, Dr. Edmund B. Spaeth exenterated the entire left orbit. This was followed by large dosage X-ray therapy, and the patient developed marked X-ray sickness.

In January, 1947, six small metastatic nodules were noted in the left scalp under the skin. X-ray films now disclosed a small area of metastasis in the left sphenoid bone. The exenterated socket granulated well, with no recurrence of tumor lesions in the socket at any time. In March, 1947, X-ray studies revealed metastases in the left frontal bone. In June, 1947, the patient had a severe spell of vertigo, falling to his right side and vomiting. Then he had frequent episodes of speech aphasia with loss of memory and with weakness in his right arm.

Examination disclosed paralysis of the left fifth cranial nerve including the motor division, diminished right corneal sensitivity, slight deafness in the left ear, weakness of the right arm, slight dyssynergia of the left arm, and an ataxic gait. X-ray studies now showed further metastases to the left sphenoidal ridge and to the posterior portion of the left ninth rib. A spinal tap revealed clear fluid under normal pressure with a heavy globulin reaction, and a colloidal gold curve of 5,443,322,000. A ventriculogram was negative, but metastases to the left cerebrum and to the posterior fossa were strongly suspected.

The patient steadily went down hill with frequent episodes of speech aphasia and

with progressive weakness of his right arm and his right leg.

During all this time his right eye remained normal, although possibly the retinal veins and arteries were slightly more full and slightly more tortuous than they had been one year before.

A few days before death he became drowsy and developed a paralysis of the right sixth nerve. He died in a coma August 29, 1947. Autopsy permission was refused. The immediate cause of death was thought to be due to increased intracranial pressure, which in turn was due to cerebral metastases.

This case well illustrates that mixed tumors of the lacrimal gland tend to recur if followed long enough and that they tend to become malignant. These tumors have a strong tendency toward bony invasion. Roentgen therapy has little effect on this type of tumor. If the tumor invades the soft tissues of the orbit, immediate exenteration is indicated. If there is bony involvement, a complete bone resection of the involved osseous portion is advisable. Finally, the best surgical approach is through the roof of the orbit by a frontal bone flap.

(I wish to thank Dr. Spaeth again for giving me the privilege of presenting this interesting case.)

Discussion. Dr. I. S. Tassman: Mr. Chairman, may I present a case, which in several ways is similar to the case that was presented by Dr. Rubin a year ago, and again with a final report tonight.

This case first came under my observation at the Wills Hospital a little over a year ago. However, the patient had attended the clinics at the Wills Hospital since 1934—a total of nearly 14 years. In 1934, he first noted a swelling of the left upper eyelid over the region of the lacrimal gland. An excision of the mass was done at that time. There was a recurrence, and a second excision was made in April, 1938. There was another recurrence. He returned in 1943, when the mass was again excised; in July, 1945, when there was a similar recurrence and again an excision of a portion of the mass. A biopsy was done each time. The laboratory report from Dr. Perce DeLong was "a mixed tumor."

In October, 1946, the patient again returned, and that was the first time that he came under my observation. He suffered another recurrence of a mass over the lacrimal gland on the left side.

This slide (showing slide) presents the general external appearance of the patient, showing a ptosis of left upper eyelid and the swelling over the upper, outer quadrant of the left orbit. Again we excised some of the mass for biopsy, and this time the report from Dr. DeLong in the pathology laboratory at Wills Hospital was, "tumor cells that are definitely adenocarcinoma."

An exenteration of the orbit was then done. The mass in the upper eyelid, and the infiltration of the soft tissue of the orbit were diagnosed by Dr. DeLong as adenocarcinoma. There was apparently no involvement of the bones of the orbit. At the present time the patient is still living and well, and in apparently good condition.

I believe this is another case of mixed tumor which, after a period of years, became malignant and was found to be an adenocarcinoma of the lacrimal gland.

Teratoma of the orbit

Capt. Frederick Harbert (MC), U.S.N. (by invitation) spoke on this subject and gave a case report.

Congenital tumors are classified embryologically according to the number of germ layers from which the tumor is derived. Thus osteoma, angioma, and so forth, are derived from a single germ layer. Dermoids are characterized by tissue derived from two germ layers; namely, ectoderm and mesoderm. These are characterized by the presence of squamous epithelium and derivatives from it, such as hair, nails, and teeth; sudoriferous and sebaceous glands. The dermis, derived from underlying mesenchyme, may become differentiated to form

cartilage, bone, fat, muscle, or other specialized tissue. Dermoids may occur as cysts or solid tumors. In the former, the dermis is on the outside and the epithelium lines a cavity, usually filled with inspissated oil secretion and hair. In the more common solid type, the epithelium is exposed to the surface of the body; a common site is astride the corneal margin. Solid dermoids are more common than the cystic variety about the orbit.

True teratomas must contain tissue derived from all three germ layers. These are exceedingly rare in the orbit and are usually malignant. The identification of tissue derived from the entoderm is sometimes difficult, and some pathologists rely on the complexity and variety of tissue in making a diagnosis of teratoma. The finding of tissue consisting of cavities lined by pure mucous epithelium with an arrangement characteristic of gut is considered diagnostic of endodermal origin. The dermoid variety of tumor is often referred to in the literature as teratoma, teratoid tumor, mixed tumor, and epibulbar tumor. A perusal of the literature for the past 10 years failed to disclose a single case of pure teratoma that is composed of tissue derived from three germ layers.

The most common locations of dermoids and teratoma are the ovaries, testes, and sacral regions, but they have been reported in nearly every part of the body. An analysis of dermoid cysts seen at the Mayo Clinic from 1910 to 1935 showed that out of 1,495 cases, 45 percent occurred in the postanal region, 42 percent in the genitalia, 7 percent in the head and neck, and 6 percent elsewhere. Among the dermoids of the head and neck, half were in the orbital region, and of these 60 percent occurred in the outer third of the eyebrow. Half of these were noted at birth. Only 10 percent of the dermoids of the orbital region (six in 25 years) were within the orbit, usually in the upper outer quadrant of the right orbit.

Case report. Baby M. was born on December 11, 1946, with a very large mass in the left orbit causing marked proptosis. At birth the conjunctiva and cornea were normal, but within 24 hours the conjunctiva became increasingly chemotic, and the cornea showed beginning cloudiness and infiltration. This process continued in spite of moist-chamber dressings during the following two days before permission for operation was obtained. The cornea was well formed, and measured 9 mm. in diameter. The globe could be palpated through the mass, and seemed to be definitely flattened anteroposteriorly. Behind the globe a solid tumor mass filling the entire orbit could be palpated. The outline of the mass was smooth except inferiorly where several nodules were felt. Transillumination of the mass gave the same consistency as the cheek. The globe transilluminated clearly. A needle passed into the mass for diagnostic aspiration failed to demonstrate fluid. The eye was not fixed, but motion was restricted to random irregular very slow oscillations.

The iris of the right eye was normally blue, but that of the proptosed eye was dark brown. The pupil was miotic, but dilated well with atropine. Slitlamp examination showed persistence of a well-marked pupillary marginal vessel. X-ray films of the orbits showed distinct enlargement of the left orbit with intact bony walls.

Physical examination was negative for other developmental defects, and the right eye was normal. A clinical diagnosis of microphthalmos with cysts was made, and exenteration of the orbit was advised at once to avoid deep infection of the eye and orbit, which was considered inevitable because of exposure and edema. Operative permission was obtained on the third day.

Operation was performed under infiltration anesthesia with no objection from the patient except to the injections. Two-percent procaine with adrenalin was injected into the lids and along the orbital walls to the apex in minimal amounts, and the conjunctiva was anesthetized by pontocaine instilla-

tions. The conjunctiva was first separated at the limbus on the temporal side, and the globe and outer aspect of the mass were exposed to ascertain the relation of the mass to the eyeball, and determine whether the mass was resectable without sacrificing the eye. It soon became apparent that the optic nerve passed through and seemed an integral part of the mass, and that the extraocular muscles and Tenon's capsule were so attenuated that they were not recognizable. An incision into the exposed mass showed it to be composed of solid tissue with multiple cysts containing clear fluid. A line of cleavage between the mass and the periorbita was readily obtained, and the mass could be easily separated.

The entire orbit was filled with tumor which extended to the orbital fissures and optic foramen. When the eye and mass were removed, a plastic implant was placed in the apex of the orbit, and the conjunctiva closed over it. A conformer was inserted in the conjunctival sac. When healing was completed and contraction of the cul-de-sac had stabilized, the conformer was replaced by an acrylic prosthesis made from a casting of the cavity. This has been worn continuously since then.

Measurement of the excised specimen showed the globe to be 18 by 19 mm. at the equator, and 15 mm. in the antero-posterior axis. The retrobulbar mass was roughly 5 by 4 cm., and contained multiple cysts on the surface.

Convalescence was uneventful, and the baby is developing normally with no evidence of recurrence to date.

Pathologic report. The microscopic sections of the excised specimen were examined by Dr. Jonas S. Friedenwald, Wilmer Ophthalmological Institute of The Johns Hopkins Hospital. His diagnosis was: Teratoma of orbit, microphthalmos, exposure keratitis, and hypopyon ulcer of the cornea.

The globe is quite small. The cornea is infiltrated and scarred. The anterior chamber is filled with polymorphs, many of which are seen in the iris stroma, but there is an abscess in the ciliary body. There are many retinal and subretinal hemorrhages, and a few tiny choroidal hemorrhages. The optic nerve shows partial atrophy.

The tumor is a large cystic mass containing fat, bone, cartilage, and many cysts lined with epithelium of varying forms. The epithelial forms include squamous epithelium with many hair follicles and sebaceous and sudoriferous glands, ciliated, columnar, and cuboidal mucous membrane with a papillary structure and arrangement characteristic of intestine. There are also small scattered glands of the racemose type resembling salivary or lacrimal gland.

The matrix of the tumor is young connective tissue. Other tissues that are embedded in this matrix are lymphoid follicles with germinal centers and nerve tissue including large ganglion cells.

Zentmayer Award

The third Zentmayer Award was presented to William M. Hart, Ph.D., for his paper "Hydration Properties of Excised Cornea and Factors Responsible for Transparency." This paper was presented at the October, 1946, meeting. See the JOURNAL, 30: 1022 (Aug.) 1947.

Fusional Vergence

DR. EDWIN FORBES TAIT (by invitation) presented a paper on "Studies in Fusion: Fusional Vergence," an abstract of which follows.

The fusional process in vision is a twofold entity. It is, first, concerned with sensory perception, which is that which should properly be designated as "fusion," and, second, the varying of the position of the visual axes of the eyes in order to retain single binocular vision, which should be considered as "fusional vergence."

Fusional vergence may be defined as the modification produced by the fusional process in the distribution of tonic reciprocal

innervation to the extraocular muscles, in order to preserve or to gain single binocular vision.

The author reports on 500 subjects, who were selected as normal individuals in view of the fact that they possessed clear, comfortable, and efficient single binocular vision and were wearing suitable glasses, if needed.

Prism convergence break and recombination tests, and prism divergence break and recombination tests were carried out with extreme care under certain standard conditions. Results were recorded with suitable allowance for the experimental variations and the patient's reaction time. The data show that in a group of 500 subjects, as prism convergence is increased, more persons will fail to maintain fusion. At 26-28$^{\Delta}$ only 10 percent can still maintain fusion but of these few, some can overcome as much as 38-40$^{\Delta}$. The midpoint of the range is about 18-20$^{\Delta}$.

With prism divergence, half of the subjects cannot maintain fusion with as much as 12-14$^{\Delta}$, although 10 percent can go as far as 18-20$^{\Delta}$, and some can go as far as 22-24$^{\Delta}$.

After the break, and the consequent diplopia, the prism power is reduced until eventually fusion is regained. With prism convergence, over 10 percent of the patients will regain fusion when 10-12$^{\Delta}$ remain, and 100 percent have regained fusion at 2-4$^{\Delta}$.

With prism divergence, the extramacular fusion area is apparently smaller, as only 20 percent have regained fusion at 6-8$^{\Delta}$, 50 percent at 4-6$^{\Delta}$, and the remaining 30 percent at 2-4$^{\Delta}$.

The data suggests that the response of the extraocular muscles to gradually increased prism power base-out or base-in is dependent primarily upon the stimulation of receptors which immediately encircle the macular area. Reversion to fusion, however, once diplopia has been established, is dependent upon the sensitivity of more peripheral receptors than the perimacular ones, and the area in which these are found is considered as the extramacular fusion area.

On the basis of these studies, we may consider perimacular and extramacular receptors, and the ocular movements which result from their excitation, as the essential parts of the stimulus-response mechanism which is charged with the maintenance of single binocular vision.

Using the results of the reversion to fusion tests, it is possible to plot the lineal dimensions of the extramacular fusion area upon each retina under given conditions of fixation and stimulation.

In general, it was suggested that the function of the perimacular fusional receptors, those immediately surrounding each macula, is to retain single binocular vision, once it is established, while the function of the extramacular fusional receptors, further in the periphery, is to aid in obtaining single binocular vision.

The use-amplitude fraction in fusional vergence is described and defined as the amount of fusional vergence constantly in use (in order to correct the faulty position of the visual axes for the point of fixation), over the amplitude of fusional vergence available in the same direction. In esophoria, relative to fixation at 6 meters, for example, a patient has a constant repeated stimulation of his nasal perimacular receptors of either or both maculas. If he has an adequate amplitude of fusional convergence, which means a sufficient number of perimacular receptors available, his esophoria may be compensated for without difficulty.

The use-amplitude fraction may be used practically in orthoptic problems to determine the probability of comfort or discomfort in binocular vision, and also to indicate the extent to which the fusional vergence amplitude values will have to be developed in order to compensate for heterophoria.

Discussion. Dr. Robert H. Peckham: Dr. Tait's paper is of perhaps unrecognized, but really quite tremendous, theoretical importance.

The function of binocular fixation in maintaining singleness of visual perception

with two stimuli is a matter of clinical importance, because of the asthenopia resulting from interruptions of that function. This function is also of considerable theoretical importance in explaining the phenomena of binocular vision. The oldest theoretical explanation is that of exactly corresponding retinal points. This theory was modified by Panum, who proposed that a point and an area are involved; that is, that an area in one eye is associated with a point in the other.

A paper which I had the privilege to read to this society, in 1934, summarized experimental evidence that binocular vision could occur with noncorresponding points, and that noncorrespondence could be quite great without loss of stereoscopic vision, or without loss of binocular fusion.

Now Dr. Tait has offered experimental evidence concerning the mechanism for the return to binocular fixation, after breaking binocular fusion with prism convergence or prism divergence. He has offered an explanation of this return which does not require the stimulus of exactly corresponding points, because, if the stimulus of corresponding points were required for the return to binocular fixation, it would be necessary for the prisms to be reduced completely to zero value before the two maculas could be stimulated with the same image, and binocular vision result. He has suggested a function which would permit the binocular fixation to return without the retinal images being moved, by the prism power, to both maculas, or to exactly corresponding points. Unfortunately, he has not been able to demonstrate the actual eye movements involved, so that we are not in a position to trace fully the course of events in terms of perception and movement, and thus infer the stimulus and response mechanisms involved throughout the prism divergence and convergence. Nor did the measurments I made in 1934 carry the problem to completion, because I did not allow my subjects to break in their fusion.

However, it now becomes possible for us to anticipate a method of attack on the problems of stimulus-response mechanisms in binocular vision, since Dr. Tait has shown that the fusional areas near the maculas are of statistical nature; that is, with increasing distances from the maculas there are decreasing probabilities of stimulus for return to binocular fixation. It may be possible with more experimental work, perhaps with objective eye-movement studies correlated with Dr. Tait's observations, to explain the entire binocular function in terms of the fusion of corresponding and noncorresponding points, and the probabilities of the stimulus values of such points for the maintenance of binocular fixation.

Dr. Francis Heed Adler: I am particularly interested in this work, which merits consideration, because the author has been carrying out in experiments on normal subjects what we hope sometime to be able to do in cases of strabismus. The first part of his presentation deals with the reflex fusional movements of the eyes, which are independent of the will and brought about, as the author states, reflexly by the potency of the receptors in the region of the fovea. He has succeeded in mapping out the area of that reflex innervation. On top of that is a voluntary innervation. It is this innervation which the patient brings into play when he is given prism exercises. Although both of these mechanisms work hand in hand and simultaneously, the reflex mechanism is the one which is the more important, and which is the true measure of fusion. Ordinarily, fusion is measured subjectively. This provides a method of measuring fusion objectively. We should be able to determine an individual's fusional capacities by the reflex movement of his eyes, if we can eliminate the voluntary mechanism. Such studies would afford us a quantitative measure of the fusional movements which keep the eyes in alignment and would be, therefore, an objective measure of fusion, independent of any subjective phenomena.

We are hoping in the very near future to be able to measure the fusional capacity of children with squint. We wish to know whether the objective measurements of these children correspond to their subjective responses to fusional stimuli. Further than this, we wish to know whether orthoptic exercises can change these objective values as well as the subjective values.

I feel that Dr. Tait has made a valuable contribution to our knowledge.

Dr. Edwin Forbes Tait: I should like to thank Dr. Peckham and Dr. Adler for their helpful discussions.

Regarding the question which Dr. Adler asked relative to changes in the basic tonic convergence after orthoptic procedures, in my experience there has been, in most cases, very little change in the lateral heterophorias after such exercises. However, it seems that when the appropriate fusional convergence amplitude is increased by exercise, which can easily be done in the convergence insufficiency cases, the patient usually is more comfortable, probably because of increased ability to compensate for his heterophoria.

Mass survey for detection of glaucoma

Dr. Carroll R. Mullen gave a preliminary report concerning activities and results associated with a mass study for the presence of glaucoma being conducted by the Philadelphia Committee for Prevention of Blindness under its executive director, Miss Evelyn Carpenter, with the guidance and advice of its medical advisory committee. The actual examinations were conducted by Dr. Victor I. Seidel, Dr. Harry A. Felice, and Dr. Solomon S. Brav.

A total of 2,455 individuals were studied and 33 cases of chronic simple glaucoma have been diagnosed, together with one case of secondary glaucoma. All of those examined in this survey were volunteers. The largest group examined was made up of the employees of several department stores, totaling 1,788. Employees of home offices of several insurance companies totaled 508, and another group of 159 from one industry was observed.

Difficulty in inducing employers to allow their workers to take time and set aside space for these examinations had been anticipated, but this did not occur. Actually, the employees were solicited to volunteer for examination.

In the department store group, 41 were below the age of 35 years, 508 were between the ages of 35 and 45 years, 705 were between 45 and 55 years, 435 between 55 and 65 years, and 98 were over 65 years of age. Three ages were undetermined, probably falling in the last older age classification. In this group, a diagnosis of chronic simple glaucoma was made in 33 employees, and one worker had secondary glaucoma. There were 13 men and 20 women; 1 woman, designated as having glaucoma, belonged in the undetermined age group; 2 men and 3 women were between 35 and 45 years of age; 3 men and 8 women were between 45 and 55 years; while 6 men and 8 women were between 55 and 65 years; 2 men were more than 65 years of age.

Of the insurance company office workers examined, 4 were under the age of 35 years; 194 were between 35 and 45; 177 were between the ages of 45 and 55; and 120 were between 55 and 65 years of age; while 13 were aged over 65 years. Glaucoma was diagnosed in two of these workers with a possible diagnosis in one other case. The two cases were men between the ages of 55 and 65 years, and the one probable case was a woman between the age of 35 and 45.

In the one industry in which a total of 159 employees volunteered for examination, the group included two under 35 years of age; 16 between the ages of 35 and 45; 61 between the ages of 45 and 55; 53 between the ages of 55 and 65; and 27 over the age of 65. In this group, one probable case of glaucoma (a 66-year-old man) was found. Two additional cases have now been diagnosed, and they are in the age group of 45 and 55 years.

The procedure for this study was to make an initial plea to workers to volunteer for examination. Visual acuity was first recorded, then an external examination was made by an eye physician. An ophthalmoscopic study through the undilated pupil was recorded. Intraocular-pressure examinations were made using a Schiøtz tonometer. In all cases in which tension was recorded at 25 mm. Hg or higher the volunteer was reexamined. If his record still remained higher than 25 mm. Hg, the individual was referred to an eye clinic or to his own private ophthalmologist for visual-field studies, provocative tests for glaucoma, further tension recordings, and treatment.

It is probable that there are people working in the above establishments who have glaucoma, know that they have it, and are already under treatment, and, not wishing to discuss the fact with their employers, did not volunteer for examination. It is of interest to note that none of the 33 cases of chronic simple glaucoma had any knowledge of the condition of their eyes. Only five of these employees had every consulted an ophthalmologist for any previous type of eye care.

This mass survey for the presence of glaucoma is a progressive step in the endeavor of the Philadelphia Committee for Prevention of Blindness to locate diagnosed cases of glaucoma, to follow them up, and to aid the ophthalmologist in preventing total loss of vision.

Until February, 1940, there was no organized follow-up service for glaucoma patients in eye clinics in Philadelphia. In his presentation Dr. Mullen reviewed the formation of this service under the Philadelphia Committee for the Prevention of Blindness. He likewise reviewed the number of glaucoma cases that had been observed and followed in the Wills Hospital in conjunction with this survey.

This report outlines the endeavor to determine the number of individuals with undiagnosed glaucoma who are not aware of their condition and have not had medical attention. With more than 2,400 patients studied, the over-all total is 1.3 percent, which is somewhat less than previous figures estimated for the general population. Gathering of this information may be of great service to all workers in the ophthalmic field who are especially interested in the study of glaucoma.

George F. J. Kelly,
Clerk.

Historical Miniature

Although Fabricius ab Aquapendente recognized the true position of the lens he looked upon it as the organ of vision. The surgeons were expected to be very ignorant of optics. Kepler, the great astronomer, thought that an error in optics made by Felix Platter, a distinguished student of the physiology of vision, was excusable because he was a physician.

KATHERINE FERGUSON CHALKLEY, *Manuscript Editor*
Lake Geneva, Wisconsin

Directors: LAWRENCE T. POST, President; WILLIAM L. BENEDICT, Vice-President; WILLIAM A. MANN, Secretary and Treasurer; WILLIAM H. CRISP, FREDERICK C. CORDES, DERRICK VAIL.

Address original papers, other scientific communications including correspondence, also books for review to *Dr. Derrick Vail, 700 North Michigan Avenue, Chicago 11, Illinois;* Society Proceedings to *Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin.* Manuscripts should be *original copies,* typed in *double space,* with wide margins.

Exchange copies of medical journals should be sent to *Dr. F. Herbert Haessler, 324 East Wisconsin Avenue, Milwaukee 2, Wisconsin.*

Subscriptions, application for single copies, notices of changes of address, and communications with reference to advertising should be addressed to the *Manager of Subscriptions and Advertising, 664 North Michigan Avenue, Chicago 11, Illinois.* Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the *Manuscript Editor, Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin.* Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Ahnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

THE OXFORD OPHTHALMOLOGICAL CONGRESS

The 34th annual meeting of the Oxford Ophthalmological Congress was held on July 8th, 9th, and 10th at the School of Geography in Oxford. Members were housed at Hertford College nearby. About 100 ophthalmologists attended.

The meeting was called to order by the Master, Mr. F. A. Williamson-Noble, who then gave the address of welcome.

The morning of the first day was devoted to a discussion on "The Use and Abuse of Topical Ocular Therapy." Mr. F. Ridley gave an excellent talk on the structure and function of the tear film and its surface tension and absorption properties. He spoke of the biochemistry of the tears, on which he is a recognized authority, and how their bacteriocidal properties are related to their interaction with applied remedies and to the physical structure of ointments. He emphasized that the lysozyme content of tears is definitely diminished in local epiphora and that atropine affects the lacrimal gland by decreasing epiphora and relatively increasing lysozyme. Hence atropine might well be used in certain stubborn cases of conjunctivitis.

Dr. F. E. Preston continued the discussion with a historical resume of local therapeutic agents and made a plea for more uniformity in drug terminology.

Further discussion was contributed by Dr. J. M. Robson of Guys Hospital, whose contributions to the literature of chemical warfare are so well known. He gave a thorough review of local therapeutic methods. In discussing the use of detergents, he pointed out that increased corneal permeability was not due to their surface-tension reducing effect alone, since, if one removes the corneal epithelium of a rabbit, the addition of a detergent does not increase permeability of drugs. With regard to intravitreal injection he felt that streptomycin was toxic to the retina, but that pure crystalline penicillin was not.

In the afternoon Dr. J. J. Healy presented the case histories of a series of unusual ocular injuries. Dr. Grant Peterkin gave a talk on "Dermatological Conditions Affecting the Ocular Adnexa," and Mr. Dickson Wright spoke on "The Approach to Orbital Tumors." Mr. Wright's talk was outstanding for its clarity of expression, and the excellence of the moving-picture film shown. He freely removes the orbital rim for better exposure.

Mr. Frank Law presented a report on a case of retinoblastoma at the second morning session. The highlight of the meeting occurred when Sir Stewart Duke-Elder gave the Doyne Memorial Lecture on "The Blood-Aqueous Barrier." This consisted in an outline of the development of our conceptions of the intraocular fluid and a comparison of earlier techniques with more modern methods, particularly those employing tracer elements.

The author stated that results obtained by these newer techniques have shown that his original theory, that the aqueous is a simple dialysate, is wrong, and that the process is a far more complicated one involving a combination of dialysis and secretion.

The afternoon was devoted to a discussion on "The Operative Treatment of Chronic Glaucoma," by Mr. F. A. Williamson-Noble and Mr. Maurice Whiting. Many others also participated. The consensus of opinion was that the trephining operation gave the best results, but the iris-inclusion operation had its advocates. What impressed a visitor was the apparent disregard of the anterior-chamber depth and the condition of the iris angle in contemplating surgery. This was never mentioned.

On the final day there was a morning session only. Prof. A. Lowenstein gave a beautifully illustrated talk on "Some Facts and Aspects of the Anterior Drainage System in the Human Eye." Mr. J. Minton spoke on "Occupational Eye Diseases of the Lens and Retina." Dr. Gunnar von Bahr of Sweden discoursed ably on the "Measurements of the Effect of Solutions of Different Osmotic Pressure on the Thickness of the Living Cornea." Dr. Winnifred Fish gave a short paper on "Hereditary Mesodermal Atrophy," reporting four cases, and Dr. Margaret Dobson spoke on "Dynamic Retinoscopy."

The social aspects of the congress were, as usual, delightful. Tea was served in Hertford College in the late afternoons following the scientific sessions and was enjoyed amid the charm of old-world surroundings. The annual dinner took place in the refectory of the college on the night of July 8th.

The Oxford Congress, founded by Doyne in 1914, continues to hold a secure place in British ophthalmology.

Edwin B. Dunphy.

READING EFFICIENCY

A study of the reading skill of adults shows that the ocular movements account for but 10 percent of the reading time—the fixation pauses for 90 percent. As reading skill progresses from the grades to college, the fixation pause decreases from two-thirds second to about one-fifth second and the regressive movements decrease from an

average of five per line to one-tenth as much. Retinal perception requires less than one-tenth second, although the fixation pause is at least double this period. The convergence is not fixed but relaxes slightly with each fixation pause so that between the beginning and end of each line there is a rhythmic lessening of convergence of about one-half prism diopter. Peripheral vision provides unconscious clues and so prepares for the next fixation pause. Hence a narrow span of the visual field retards the speed of the reading process.

In both children and adults the rate of reading is not much affected by the size of type, between 6 point and 36 point but, for the most efficient reading, size of type, length of line, and interlinear space must be correlated. As there is a certain correspondence between area and reading speed, size of type and interlinear space, may, to some extent, be substituted for each other. An excessively short line (37 mm.) does not permit maximum use of peripheral vision, while with excessive length of line (180 mm.) the long return movement is accompanied by increased regressions at the beginning of successive lines. Between such extremes, size of type and length of line can be balanced for maximum effectiveness. In a test on second graders with a 61.5-mm. line, 3-point leading, the 12-point type placed first in speed, 14-point was second, and 18-point a poor third. For adult reading, 10-point type on an 80 mm. line with 2-point leading is considered optimal.

The most readable type is that which is fairly simple in design. Paradoxically, features that increase clarity for distance may, nevertheless, slacken the reading pace. Words in capitals when compared to lower case are read at a greater distance, but for speed of reading the order is definitely reversed. In distance tests, the least visible type form was Scotch Roman, a lightface type, while the most visible was American Typewriter; yet, the former led the latter in reading speed by 5 percent.

As checked by the rate of reading, black print on a white or cream background is superior to any other combination. The quality and texture of the paper is of relatively minor import.

The best quality of illumination for reading is daylight from the north sky. In the most favorable light distribution, the brightness of the central field and that of its surroundings are approximately equal. For exceedingly fine work, the normal eye does not require more than 20 foot-candles, but for ordinary reading 8 to 10 foot-candles are considered adequate. A study lamp with a 60-watt Mazda bulb provides by itself about 7 foot-candles on the reading surface.

The study of eye movements by photography of the corneal reflections has several drawbacks. The procedure necessitates the elimination of head movement, the presence of light in the visual field, and the restriction of the reading span to less than 20 degrees. But the electrical method about to be described allows any amount of continuous and unrestrained reading under any desired conditions.

When the reader has small electrodes affixed to his outer canthi and these electrodes are connected with an equipment like that used in electrocardiography and electroencephalography, a tracing results—the electro-oculogram—that is quite similar to the familiar photographic record. As the eye moves, the electrodes are affected reversely by the intrinsic corneoretinal potential, since the electrode on the side of the approaching cornea receives more positive units and that on the side toward which the retina advances, more negative units. The voltage change follows closely the extent of the ocular excursion. When the apparatus is equipped with an ink-writing oscillograph it can furnish an automatic record of continuous reading of many hours' duration, and with extra leads the heart beat, brain waves, and the blinking reflex can be simultaneously registered.

Using such a complete set up, the problem of fatigue in reading was exhaustively studied by the educational psychologists,

Leonard Carmichael and Walter F. Dearborn. Forty high-school and college students read for six hours continuously, first a historical novel and then a formal treatise on economics. Comprehension was checked by a multiple choice questionnaire interspersed at about every 25 pages. Conditions were optimal—both books were in the same approved format, and the well-distributed illumination provided 16 foot-candles on the reading surface.

Statistical analysis of the six-hour records revealed no significant change in reading behavior, nor any distinction in performance between the type of material, between the high-school or college group, between books and microfilm, or between those wearing and those not wearing glasses.

In a previous study by Hoffman, 30 subjects who read for four hours continuously without comprehension checks displayed increasing reading deterioration after the first hour, as was shown by increased blinking, decreased reading rate, word skipping, and wandering attention. Evidently the comprehension tests, by inspiring motivation, made the striking difference in the objective results. The first evidence of fatigue in reading is an altered attitude toward the task, not in any breakdown of the neuromuscular visual mechanism. Motivation is the all-important variable and, when present, reading can be maintained for hours at a high level of efficiency. The action of the ocular musculature, like that of the heart, is intermittent and so permits adequate recuperation.

James E. Lebensohn.

OBITUARY

ELIAS SELINGER

(1898-1947)

Elias Selinger, son of Joseph Selinger and Rosa Feuereisen Selinger, was born in Moravska-Ostrava, Czechoslovakia, August 23, 1898, and came to the United States at the age of 15 years. He received the degree of Doctor of Medicine from Northwestern University in 1924 and decided at once to specialize in ophthalmology. After internship and residency at Cook County Hospital, he furthered his training in Vienna in 1926, and again in Paris and Vienna during 1932-1933. He became clinical assistant in the department of ophthalmology of Northwestern University Medical School in 1926. He left that department with the rank of instructor in 1929 to become associated with the eye department of the Rush Medical

Elias Selinger

College of the University of Chicago. When he resigned from that institution in 1941, he held the rank of assistant professor. Only a few months before his death, Dr. Selinger was appointed professor and chairman of the department of ophthalmology at the reorganized Chicago Medical School.

Dr. Selinger was certified by the American Board of Ophthalmology in 1931. He was attending ophthalmologist at Mount Sinai, Cook County, and Michael Reese Hospitals, and was a member of the American Medical Association, the Chicago Ophthalmological Society, the American Academy of

Ophthalmology and Otolaryngology, the Pan-American Ophthalmological Society, and the American Society for the Advancement of Science.

Among his numerous contributions to ophthalmology, the most original was the introduction of the topical application of quinine in treatment of trachoma and interstitial keratitis; his *Office Treatment of the Eye* was widely acclaimed by ophthalmologists throughout the country.

Elias Selinger was an outstanding surgeon. For his associates, it was a source of continuous amazement to see him approach each individual case on its own merits instead of following a standardized procedure. This and his meticulous deftness of technique, as well as his painstaking postoperative care of each patient, accounted for his superior surgical results.

As a consultant he always respected the opinion of the referring surgeon but seldom failed to make constructive suggestions. He had a rare gift as an organizer. Not given to compromises, he was never satisfied with half measure in whatever he undertook, and succeeded in inspiring his associates with the same spirit. He was always interested in the problems of the younger men in his specialty and ready not only to advise but to take active steps to assist them on the road to the practice of ophthalmology.

His activities in various committees allowed him little time for relaxation, and that was spent with his family.

There was little warning to his immediate family, and it came as a complete shock to his numerous friends, colleagues, and patients when a coronary thrombosis caused his untimely death in El Paso, Texas, on December 21, 1947. In his death, ophthalmology loses one of its most promising members, just at the summit of his career.

He is survived by his wife, Mildred Williamson Selinger, and a daughter, Suzan Mae.

Stefan Van Wien.

CORRESPONDENCE

Near point of accommodation

Editor,
American Journal of Ophthalmology:

In their highly scientific paper on "Effects of Practice and the Consistency of Repeated Measurements of Accommodation and Vergeance," by Brozek, Simonson, *et al.* (Am. J. Ophth., 31: 191 (Feb.) 1948), the authors say: "The true accommodation near point should be determined as the distance from the anterior focus of the eye, located about 14 mm. in front of the cornea, to the point of blurring. The correction is essential when the power of accommodation is expressed in terms of diopters. . . ."

Now the point from which the near point of accommodation should be measured has not yet been completely standardized. But most authorities figure that for determination of true accommodative power the near point should be measured from the first principal point of the eye. It may be sufficiently accurate (to within less than 2 mm.) to measure the distance from the cornea, but measurement from the anterior principal focus of the eye seems less desirable.

The increase of refractive power, which is termed accommodation, takes place at the principal planes of the eye. The power of all refractive systems is determined by the principal focal length; that is, the distance measured from the corresponding principal point. The refractive power of the static eye and the far point of the static eye are thus expressed and there is no reason not to use the same reference points for the power of the dynamic (accommodated) eye.

It is true that in calculations for conjugate foci, and the near point is the conjugate focus to the retina of the accommodated eye, several fixed points of reference can be used, including the principal foci. It is also true that where lenses are worn it is convenient to make measurements from the plane of the lenses which are practically in the first principal focal plane of

the eye. But these considerations are not sufficient to change the generally accepted reference points which are the principal points. Where measurements are made from the plane of the correcting lens, 15 mm. (in round numbers) is added to get the distance *from the principal point.*

Another consideration is that, while measuring the near point, from F_1 of the eye is convenient for figuring the power of the lens which replaces accommodation; when used for measuring accommodative power it does not disclose the intrinsic difference in accommodative activity as between the natural emmetrope, the corrected hyperope, and the corrected myope. For example, a near point, say, of 10 cm. measured from F_1 of the eye of the natural emmetrope, the 4.0D. corrected hyperope and the 4.0D. corrected myope, would give each one 10 diopters of accommodation.

Actually, this near point shows that the natural emmetrope can accommodate—that is, increase the power of his eye by 8.7 diopters; the 4.0D. corrected hyperope can accommodate 10.09 diopters, and the corrected myope can accommodate only 7.66 diopters.

An accurate determination of accommodative power in all cases is best determined by measuring the near point from the principal plane of the eye, which measurement gives the number of accommodative units the patient has. The value in diopters is then found from the dioptral value of the accommodative unit (Pascal: Tr. 2nd Pan-American Congress of Ophthalmology, 3:53-77; Eye, Ear, Nose & Throat Monthly, 25:354-362 (July 1946).

Whatever method is used, the discrepancies may not be large, but in the interests of scientific accuracy they are worth noting.

(Signed) Joseph I. Pascal,
New York.

BOOK REVIEWS

DISEASES OF THE EYE. By Sir John Herbert Parsons and Sir Stewart Duke-Elder. New York, Macmillan Company, 11th edition, 1948. 732 pages, 368 figures, 21 plates, and index. Price, $7.00.

Parsons' *Diseases of the Eye* is a perennial favorite with ophthalmologists and general physicians and their teachers, both in this country and abroad. It is a little more elaborate than the textbooks of May and of Gifford, since it is written more for the general practitioner than for the medical student. Because of this, however, it is of particular value to the physician who wishes to have in his reference library a book on ophthalmology that covers the unusual conditions, as well as those subjects more commonly encountered.

Since the 10th edition that appeared in 1942 and was reprinted in 1944, many advances have been made in the practice of ophthalmology, especially those produced by chemotherapy, new concepts of the etiology of choroiditis, and many others. The authors have taken great care to incorporate these advances in the new text and, in weeding out the old beliefs, have retained what has been shown by the passage of time to be useful.

It is pleasing to see, yoked with the notable name of Parsons, that of Duke-Elder. These two eminent and authoritative ophthalmologists, each a top-flight author in his own right, together insure that the information contained in their book is accurate and unquestioned. It cannot be recommended too highly.

Derrick Vail.

HANDBOOK OF OPHTHALMOLOGY. By Everett L. Goar. St. Louis, C. V. Mosby Company, 1948. 166 pages, 45 text illustrations, and 7 color plates. Price, $5.50.

There have been several attempts during the past few years to present the field of

ophthalmology in outline form for the benefit of undergraduate medical students. This trend recognizes the overburdened medical curriculum and the fact that the limitation of time and the somewhat meager interest of most students in such a specialized subject preclude adequate perusal of the more extensive texts. These handbooks, therefore, have a very definite place in undergraduate teaching and, perhaps, may be of help to the general practitioner who desires a broad perspective of this branch of medicine; for the graduate student and practicing ophthalmologist they are, of course, too incomplete to be of value.

The present *Handbook of Ophthalmology* was first written as a series of lectures for medical students at Baylor University and presents in an abbreviated and concise form the essential facts about the eye with which the student should be familiar. Dr. Goar has done his editing judiciously, and little fault can be found either with the subject matter included or omitted or with the manner of presentation. The book is well printed on a good grade of paper and contains numerous and fairly adequate illustrations.

Somewhat unusual in a work of this limited scope is the introductory historical chapter, and the author is to be congratulated for including this cultural background. Separate chapters deal with anatomy, embryology, and physiology. A chapter on "Methods of Examination" describes not only routine but also the more refined instruments of diagnostic value, and a separate chapter deals with the ophthalmoscope and normal fundus. Twelve pages are devoted to refractive errors and the principle of their correction. External diseases are discussed in orderly fashion, and the common fundus lesions are described and illustrated. Subsequent chapters deal with glaucoma, intraocular tumors, strabismus, and the eye in general disease. The final chapter discusses eye injuries and first aid and ocular therapeutics, including a few helpful prescriptions.

This *Handbook of Ophthalmology* appears most useful for the purpose for which it is intended and deserves wide use in medical schools. William A. Mann.

THE ANATOMY OF THE EYE AND ORBIT. By Eugene Wolff. Philadelphia, The Blakiston Company, 3rd edition, 1948. 440 pages, 323 illustrations including 24 in color, bibliographies, and index. Price, not listed.

Wolff's *Anatomy of the Eye* is too well known to require much discussion. The handsome third edition, beautifully printed and illustrated, is superior in many ways to its predecessor. The chief changes in the text are "in the descriptions of the ciliary muscle, the substantia propria of the cornea, the vitreous, the zonule of Zinn, the distribution of the lacrimal fluid, the mucocutaneous junction at the lid margin, the precorneal film, the retinal capillaries, and the central connections of the visual apparatus" in the light of the latest information.

It is certain that every student and practitioner of ophthalmology will require this authoritative book in his daily work for study and reference. Derrick Vail.

THE BLIND PRESCHOOL CHILD. Edited by Berthold Lowenfeld, Ph.D. New York, American Foundation for the Blind, Inc., 1948. 148 pages. Price, $2.00.

The ophthalmologist having easy access to the social services discussed in this collection of papers presented at the National Conference on the Blind Preschool Child, March 13 to 15, 1947, will have no urgent need for the book, although he will find it stimulating and interesting reading.

Ophthalmologists in more isolated communities, however, to whom these services are not available, can glean many constructive suggestions from the pages of this slim volume—suggestions that will give them a

more understanding and sympathetic insight into the problems faced by the parents of blind babies.

The contents are arranged according to three phases of the problem of the blind preschool child—the social work, educational, and medical aspects. There is also a summary of the conference written by Berthold Lowenfeld and a message from Helen Keller.

Under the division, "Social Work Aspects," authorities in this field discuss such pertinent subjects as: "The Influence of *Institutionalization on the Young Child*," "Parental Attitudes," "Individual Case Work with Parents," and "Group Work with Parents." Legislative provisions for the blind preschool child, social workers' responsibilities, and reports from four states—Illinois, New Jersey, New York, and Wisconsin—in regard to the number of cases, cause and degree of blindness, and age groups complete this section of the book.

"Educational Aspects" include thoughtful studies on "The Emotional and Social Development of the Young Child," "Training Problems and Techniques," "Measuring the Mental Development of Blind Preschool Children," and "Facilities for the Education of Blind Preschool Children."

Under "Medical Aspects," Dr. Arnold Gesell discusses "Development and Guidance of the Blind Infant"; Dr. Brittain F. Payne, "Early Diagnosis of Visual Defects"; Dr. Robert R. Chace, "The Hereditary Aspects of Blindness"; and Dr. Merrill J. King, "Retrolental Fibroplasia."

Negative attitudes never solve any problems. Because this book offers dynamic counsel, the ophthalmologist can recommend it without hesitancy to the parents of the blind preschool child.

Katherine Chalkley.

THE SKULL, SINUSES, AND MASTOIDS. A HANDBOOK OF ROENTGEN DIAGNOSIS. By Barton R. Young, M.D. Chicago, The Year Book Publishers, Inc., 1948. 148 plates, bibliography, index. Price, $6.50.

There has long existed a need for this book. Only the exceptional ophthalmologist is competent to make a roentgen diagnosis of the area within his field. Every day in an active practice, this problem is met, and the ophthalmologist has had to be dependent upon the interpretation of the X-ray findings reported by the X-ray department to help him.

Superbly printed on excellent paper and beautifully illustrated, the volume is a most lucid exposition of its title. Unfortunately, the subject of foreign bodies in the orbit or within the globe is not discussed. Ophthalmologists would like to see a chapter devoted to this matter with a discussion and evaluation of the many methods of localization. Perhaps, in the next edition, the author can be persuaded to add this information.

As a compensation for this lack, however, the reader will gain a better understanding of the X-ray pictures of diseases and conditions affecting the orbit and the sinuses than perhaps he has hitherto enjoyed. It is recommended reading. Derrick Vail.

ABSTRACT DEPARTMENT

EDITED BY DR. F. HERBERT HAESSLER

Abstracts are classified under the divisions listed below. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

1. Anatomy, embryology, and comparative ophthalmology
2. General pathology, bacteriology, immunology
3. Vegetative physiology, biochemistry, pharmacology, toxicology
4. Physiologic optics, refraction, color vision
5. Diagnosis and therapy
6. Ocular motility
7. Conjunctiva, cornea, sclera
8. Uvea, sympathetic disease, aqueous
9. Glaucoma and ocular tension
10. Crystalline lens
11. Retina and vitreous
12. Optic nerve and chiasm
13. Neuro-ophthalmology
14. Eyeball, orbit, sinuses
15. Eyelids, lacrimal apparatus
16. Tumors
17. Injuries
18. Systemic disease and parasites
19. Congenital deformities, heredity
20. Hygiene, sociology, education, and history

6

OCULAR MOTILITY

Caballero del Castillo, D. **Bilateral, symmetrical, partial paralysis of the oculomotor.** Arch. Soc. oftal. hispano-am. 8:396-402.

A case of bilateral paralysis of the superior, internal and inferior rectus muscles of 11 years' standing, due to lues, is reported in a woman, 76 years of age. There was also paresis of the elevators of the upper lid. The pupils were miotic, with Argyll Robertson reactions. The anatomy and vascular supply of the oculomotor nuclei are reviewed in detail, and it is concluded that the lesion was produced by an endarteritis of the basilar artery. The intraocular muscles were spared because the vascular supply of their nuclei comes from the posterior cerebral arteries. The sparing of the inferior oblique muscles makes questionable the accuracy of Bernheimer's scheme for the nuclei of the oculomotor nerves in which the nucleus for the inferior oblique is placed in front of the nucleus for the inferior rectus muscle. This lesion suggests that the nucleus of the inferior oblique is situated most posteriorly. (3 figures.) Ray K. Daily.

Danis, P. **Congenital muscular anomalies—the syndrome of Stilling-Türk-Duane.** Ann. d'ocul. 181:148-181, March, 1948.

In this outstanding contribution, the 175 references employed illustrate the author's thoroughness and understanding. Primary global retraction of orbital origin characterizes the unilateral form of this syndrome. The cardinal symptoms are diminished abduction, global retraction on adduction, and decrease of the palpebral opening. Less frequent are ocular protrusion and palpebral enlargement on abduction, vertical deviations on adduction with or without convergence weakness. The secondary angle of strabismus is greater than the primary, which is characteristic of orbital lesions. Spontaneous diplopia is absent. The left eye is much more frequently affected, and the disturbance is more common in women. The external rectus is aplastic, frequently only a band of fibrous tissue, and the internal rectus insertion is frequently too far posterior. If the external rectus subnormality is dominant, divergent strabismus follows; if the internal rectus is dominant, convergent strabismus results; if both are involved, the strabismus may be external or internal.

With passive motion made with a fixation forceps adduction without retraction suggests abnormal insertion of the internal rectus, adduction with retraction suggests primary external rectus involvement, and abduction with difficulty, internal rectus inextensibility. Global retraction is essentially due to displacement of the ocular center of rotation backwards and laterally, with resulting unequal ocular alignment. Because of the slightly oval shape of the globe combined with unequal traction, the eye is potentially forced backward during adduction and forward during abduction. Associated vertical imbalance indicates that the oblique muscles are involved. Palpebral involvement is a passive process.

In the bilateral form, males and females are equally affected; the manifestations are frequently not symmetrical and other constitutional subnormalities such as bilateral absence of the lacrimal glands and deformities of the extremities are often associated. Different forms of hereditary transmission are known to exist, the genealogical trees having been traced through three generations in several cases. The most frequent conditions associated especially with the bilateral form of the Türk syndrome are hypofunction of the facial and other cranial nerves, somatic subnormalities, and vertical ocular deviations.

Vertical involvements of primarily muscular origin are due to dysfunctions of convergence or to imbalance of the oculogyric mechanism. Congenital abduction palsy with global retraction and with vertical motor and other muscular weaknesses is one of the numerous groups of vertical and horizontal motor involvements possible.

In primary peripheral congenital abnormalities, abduction palsy may be associated with global retraction-protrusion, vertical dysfunction, and isolated palsies of individual muscles. Three basic etiologic factors must be evaluated singly and as a unit. These factors are constitution, environment, and time. Thus the more frequent left-sided occurrence of the monocular form is due to excessive pressure on the left side of the head or left orbit before or during birth, combined with constitutional or genetic tendencies, the exact nature of which is unknown. In one group the ocular involvement is but a variable part of the dysraphic syndrome. In primary mesoblastic subnormalities somatic malformations seldom exist. In epiblastic subnormalities diffuse malformations are frequently associated. Several illustrative cases are presented.

CONJUNCTIVA, CORNEA, SCLERA

Agnello, F. **Ocular mycoses in East Africa. Two voluminous epibulbar granulomas caused by fungi.** Boll. d'ocul. 27: 111-118, Feb., 1948.

In 1938 and 1940, the author observed in the eye hospital of Addis Ababa two patients with ascaris infection, who had unilateral indolent glossy hemispheric tumors of appreciable size and of red or whitish color. The masses were fixed on the sclera and did not involve the cornea. The tumors were removed in local anesthesia. Cultures could not be taken, but microscopically hyphae and spores were found. The size of the tumors may be explained by the virulence of the fungi and by climatic and enviromental factors.

K. W. Ascher.

Amsler, M., and Verrey, F. **The taking of the keratoplastic graft.** Arch. d'opht. 8:150-151, 1948.

The authors state that removal of the whole eye from the cadaver is an unecessary, mutilating procedure. They excise the two corneas at the limbus, leaving the pupils and irises intact. This is important

psychologically for the relatives of the deceased. The corneas are conserved in liquid paraffin in the refrigerator until the time of operation. Particular care is necessary not to damage in any way the zone of the grafts.

The grafts are obtained by trephining the posterior surfaces of the corneas first which makes for perfect section of the endothelium and Descemet's membrane. To facilitate this procedure the graft is placed in a depression made in a block of paraffin and the trephine used by pressure alone, without rotation, in order to avoid damaging the epithelium. The authors claim that by means of this technique the graft is adapted perfectly to the opening in the receptor eye and has received minimal trauma in manipulation.

Phillips Thygeson.

Busacca, A. **The lymphatic vessels of the human bulbar conjunctiva studied after vital staining with trypan-blue.** Arch. d'opht. 8:10-32, 1948.

Busacca studied biomicroscopically the lymphatic vessels of the normal bulbar conjunctiva after subconjunctival injections of trypan-blue and states that the conclusions drawn from previous research must be modified radically. He found the lymphatic vessels in the zone of the end capillary loops at the limbus to be situated in general in a plane posterior to the blood vessels and to be larger than the vessels and arranged radially for the most part. In the palisade zone the lymph vessels were larger than the veins of the region and were arranged radially with few anastomoses. The lymph vessels of the limbus region were found to continue without interruption into a rich network of vessels of different calibres, many of which possessed valves. Some collector vessels were found to run parallel to the limbus. In the upper fornix certain vessels disappeared towards the orbit whereas in the lower fornix the collector vessels ran horizontally towards the external canthus where they disappeared. Busacca noted further that over the entire cornea there was an extremely fine network of lymphatics just beneath the epithelium. No lymphatic ganglia, even rudimentary ones, were found in the conjunctiva and there was no episcleral network.

The author concludes that the interpretation of many authors (Gallemaert, Koby, Rollin, Cuenod and Nataf, Ascher, and others) that the limbal palisades are perilimbic lymph vessels is erroneous.

Phillips Thygeson.

Landau, J. and Stern, H. J. **Flare-up of trachomatous pannus due to ariboflavinosis.** Am. J. Ophth. 31:952-954, Aug., 1948. (1 figure.)

Much, V. **Bee venom in the treatment of herpetic keratitis and superficial punctate keratitis.** Ophthalmologica. 115: 89-100, Feb., 1948.

Much reports definitely beneficial results with bee venom (injected intracutaneously) in cases of typical herpetic (dendritic) keratitis as well as in cases of an epidemic form of superficial punctate keratitis.

Peter C. Kronfeld.

Rapisarda, Dante. **Further considerations on the keratoconjunctival tuberculids.** Ann. di ottal. e clin. ocul. 73:107-114, Feb., 1947.

The licheniform tuberculids (lichen scrofulosus) of the conjunctiva and cornea have been noted by Rapisarda as not uncommon in regions where the population has suffered from undernutrition, particularly from lack of vitamin A, and where the incidence of tuberculosis has increased.

The keratoconjunctival tuberculids (lichen scrofulosus and phlyctenular keratoconjunctivitis), especially when occurring in infancy, should be reckoned among the

ocular signs useful in the diagnosis of general diseases. They are as important as tuberculin tests and merit the attention of internists and particularly pediatricians.

Fascicular keratitis is becoming progressively rare, at least in Catania. This may indicate a modification in the nature and behavior of the tuberculids.

Rapisarda considers the keratoconjunctival tuberculids to be manifestations of an allergic state, occurring not only in infective (tuberculous) allergy, but also in various forms of noninfective allergy.

Harry K. Messenger.

Rosen, Emanuel. **Pterygium.** Brit. J. Ophth. 32:300-304, May, 1948.

The author decries the inadequacies of the McReynolds transplantation technique for the treatment of pterygia and states that recurrence of the disease is the rule even in the hands of the experiencd. He describes his own technique which resulted in only one recurrence in twenty-five cases. The head of the pterygium is dissected from the cornea with a knife and the conjunctiva is separated from the limbus above and below the growth for 3 mm. The growth is separated along its edges and a double-armed silk suture is inserted into the head toward the sclera. The pterygium is then doubled back under itself so that episcleral tissue is approximated to episcleral tissue. The sutures are brought out through the center of the caruncle and tied over a rubber button. If the pterygium is very wide, it is sliced in its middle and folded under in two sections. The edges of the conjunctiva are approximated with interrupted sutures. The sutures are removed on the tenth day. (8 figures.) Morris Kaplan.

Saba, Vittorio. **Herpetic episcleritis.** Ann. di ottal. e clin. ocul. 73:168-70, March, 1947.

Saba reports a typical herpetic keratitis occurring in an eye with a subsiding episcleritis, and concludes that the episcleritis is also a manifestation of the same virus. Harry K. Messenger.

Thygeson, Phillips. **Acute central (hypopyon) ulcers of the cornea.** California Med. 69:18-21, July, 1948.

The author presents a series of 50 cases of acute central (hypopyon) ulcers of the cornea, of which 70 percent were caused by pneumococci. The role of solution-bottle contamination in the production of pyocyaneus ulcers is discussed. Proper systemic and topical use of the sulfonamide drugs arrests progress in all but very exceptional cases. The finding of sulfonamide-resistant strains of beta hemolytic streptococci and pneumococci has been rare. Orwyn H. Ellis.

8

UVEA, SYMPATHETIC DISEASE, AQUEOUS

Costi, C. **Treatment of iris prolapse by Blascovics cicatricectomy.** Arch. Soc. oftal. hispano-am. 8:354-362, April, 1948.

The usual methods of dealing with iris prolapse are discussed, and the Blascovics cicatricectomy is described and illustrated in detail. Experience with the latter in four cases of prolapse convinced the author of its superiority over the usual methods of excision or cauterization. (6 figures.) Ray K. Daily.

Gardilčić. A. **A new iridodialysis operation.** Ophthalmologica 115:141-155, March, 1948.

The ciliary border of the dialyzed iris is "incarcerated" in a slightly scleral keratome incision and fastened there by means of corneo-iridoscleral sutures of the de Mendoza type. Two successfully operated cases are reported.

Peter C. Kronfeld.

Orzalesi, Francesco. **The pathogenesis of serous detachment of the choroid.** Ann. di ottal. e clin. ocul. 73:129-167, March, 1947.

The various pathogenetic theories of detachment of the choroid are discussed in detail. The determining factor in all cases is held to be the sudden or rapid reduction of the intraocular pressure and the resulting persistent hypotony. Detachment may occur following any perforation of the globe but especially when by reason of imperfect closure of the wound the aqueous continues to escape. The anterior chamber is usually but not necessarily abolished. However, the abolition of the anterior chamber is not a consequence of the detachment, but both are dependent on the one determining factor of hypotony. It is not the absolute hypotony that is important but rather the rapidity with which the intraocular pressure is lowered from its preëxisting level. A slow and gradual lowering, even to the extreme limit, is not sufficient to cause detachment. The effective mechanism is an exaggerated transudation from the choroidal vessels, due to a disturbance of the equilibrium between the pressure in the choroidal vessels and in the ocular cavity, when adequate compensatory mechanisms cannot properly enter into play. In a word, the detachment results from an exaggeration of the normal method of aqueous formation, and the fluid under the detached choroid should be regarded as secondary aqueous or a transudate. Little or no importance should be attributed to senile rigidity of the sclera as a factor in detachment. The sclera is never so rigid that it will not collapse when the intraocular pressure is suddenly lowered, hence the hypothesis of an aspiration *ex vacuo* from the choroidal vessels is untenable.

Even great and sudden hypotony is not sufficient to determine the formation of a choroidal detachment without the intervention of very important predisposing factors linked with anatomic changes in the choroid itself. These predisposing factors are always absent in the young and rare even in the aged. Chief of these factors is the reduced elasticity and distensibility of the choroidal tissue and of the walls of the blood vessels as found in senile involution of the choroid. In consequence, in the young a sudden and persistent hypotony does not result in transudation of fluid and detachment of the choroid, since equilibrium in pressure is rapidly restored by dilatation of the vessels and by edema of the easily dissociated choroidal tissue; whereas with rigidity transudation and detachment are more likely to occur. Without doubt arterial hypertension, which promotes transudation and consequent detachment, and increased vascular permeability of any origin are also predisposing factors. It is very probable that the site of the detachment, which is almost always anterior, is determined by the structure of the vessels in the anterior portion of the choroid, where the large and numerous veins with their simple endothelial walls are essentially blood sinuses.

Orzalesi was unable to produce detachment of the choroid experimentally in either the dog or the rabbit by establishing a fistula to drain the anterior or vitreous chamber. He attributes this failure to the structure of the eyes of these animals and to the absence of the above mentioned concomitant factors.

Harry K. Messenger.

Sien, Auw-Yang. **A case of choroidal apoplexy diagnosed as a sarcoma of the choroid.** Ophthalmologica. 115: 1-10, Jan., 1948.

A white woman, 56 years of age, complained of sudden loss of vision in her right eye. Examination revealed a normal anterior segment, absence of any red reflex from the posterior segment (upon ophthalmoscopy as well as upon transillumination) and reduction of vision to

bare light perception. The eye was enucleated. The histological examination revealed a fresh intrachoroidal hemorrhage which had originated from a ruptured atheroma of a short posterior ciliary artery. The hemorrhage had broken through the lamina vitrea and caused a well-circumscribed subretinal blood clot. The vitreous was densely infiltrated with red blood cells. Most choroidal arteries showed extensive sclerosis. The author reviews the literature on this rare condition, the spontaneous rupture of an atheromatously diseased choroidal artery or choroidal apoplexy, as he calls it.

Peter C. Kronfeld.

Vouters. **An interesting case of spontaneous choroidal detachment.** Ann. d'ocul. 181:293-299, May, 1948.

A 67-year-old man observed progressive sight loss of vision in his left eye for six weeks and a positive scotoma. In maximal mydriasis an elevation was observed in the lower peripheral part of each fundus, but more marked in the affected eye. The elevations were gray with a darker background and composed of a number of cell-like compartments or cysts. There was slight pericorneal injection, obliteration of the anterior chamber angle, corneal edema, and increased tension. During several months the vision and the gray plaques observed in the choroid remained unchanged. About one year later the patient died.

The author believes that the lesion was a choroidal detachment secondary to hemorrhage in a patient with a cardiovascular degeneration. Chas. A. Bahn.

GLAUCOMA AND OCULAR TENSION

Arkin, Wiktor. **A modification of Elliot's operation and its application to high trephination: A preliminary report.** Am. J. Ophth. 31:975-978, Aug., 1948. (2 figures.)

Boase, A. J. **Acute glaucoma in an adolescent.** Am. J. Ophth. 31:997-999, Aug., 1948.

De Leonibus, F. **Further considerations concerning a patient with sympathetic ophthalmia following sarcoma of the choroid.** Boll. d'ocul. 27:65-75, Feb., 1948.

De Leonibus reported about this patient three years ago, and described the findings in the sarcomatous eye (Boll. d'ocul., 24:266, 1945). In spite of all efforts, the vision in the other eye fell rapidly from 6/10 to amaurosis, the bulbus became soft and very painful and eventually, the second eye had to be enucleated. The time that elapsed was sufficient for complete destruction of the retina and the development of granulation tissue in its place. While plasma cells are a rarity in this lesion, they occurred with great frequency in the author's sections. (4 photomicrographs, bibliography.)

K. W. Ascher.

Lisman, Jack V. **Rubeosis iridis diabetica.** Am. J. Ophth. 31:989-994, Aug., 1948. (5 figures.)

Payne, Brittain F. **Operative failures for chronic simple glaucoma.** Am. J. Ophth. 31:965-971, Aug., 1948. (7 figures.)

Posner, A. and Schlossman, A. **The clinical course of glaucoma.** Am. J. Ophth. 31:915-934, Aug., 1948. (12 figures.)

Romero, Eduardo. **Two statements and a schematic demonstration relative to glaucoma.** Arch. Soc. oftal. hispano-am. 8:351-354, April, 1948.

Two arguments are presented. One emphasizes the functional antagonism between the circular and radial fibers of the ciliary muscle, and in the other the pathogenesis of glaucoma is attributed to a sympathetic hyperactivity of the radial muscles of the ciliary body. The conten-

tion that the circular fibers focus for near, and the radial for distance is supported by the author's studies and experiments on accommodation, and by the fact that in general, wherever there are longitudinal and circular fibers, their function is antagonistic. The author holds that in spasm of accommodation or transitory myopia only the circular fibers of the ciliary muscle participate. Spasm of the radial fibers, caused by hyperactivity of the sympathetic is manifested by a paralysis of accommodation for near, by a mydriasis because of the synergistic action of the radial fibers of the ciliary muscle and the iris and by ocular hypertension, because the canal of Schlemm is shut by its posterior wall which is formed by the tendon of the radial fibers inserted into the corneoscleral spur. All of these constitute an attack of glaucoma. Romero believes that this pathogenesis of glaucoma has not been known long because the function of the radial fibers in refraction has not been recognized. Romero demonstrates schematically how the effect of sympathetic hypertonicity on the dilator of the pupil, the vascular walls, and the radial fibers of the ciliary muscle leads to obstruction of Schlemm's canal, intraocular hypertension, and venous stasis and how the arterial ischemia and venous stasis lead to nutritive disturbances, degeneration of the ocular tissues, glaucomatous excavation, and visual loss. Ray K. Daily.

Zaretskaya, R. B. **Some experiments with green spectacles prescribed to glaucomatous patients.** Am. J. Ophth. 31:985-989, Aug., 1948. (4 figures.)

10
CRYSTALLINE LENS

D'Andrade, L. **Direct zonulotomy in intracapsular cataract extraction.** Ophthalmologica 115:78-83, Feb., 1948.

D'Andrade's direct zonulotomy consists of the breaking of the anterior zonula fibers along the lower half of the lens equator by means of a zonulotome which is introduced underneath the iris and engages the zonula fibers directly. What the actual shape of the engaging part of the zonulotome is, the reviewer is unable to tell from the article or the illustrations. The lens is tumbled and delivered by external pressure applied to the limbus by means of two separate instruments, a "dented compressor" and a "propulsor." The author recommends this method only for senile cataracts in highly myopic eyes, early and late hypermature, and intumescent cataracts. He reports a series of 129 zonulotomies. Vitreous filled the anterior chamber at the end of the operation in 4.1 percent and was lost in another 4.1 percent of the cases. D'Andrade proposes the term total phacectomy instead of the conventional term intracapsular extraction.

Peter C. Kronfeld.

D'Ermo, F. **Three cases of recurrent iritis with hypopyon as a late complication after cataract operation.** Boll. d'ocul. 27:98-110, Feb., 1948.

In the three cases described extensively, local as well as general treatment proved to be inefficient. All clinical and laboratory examinations were negative except for the successful inoculation of rabbit's cornea with aqueous humor withdrawn during a paracentesis in one of the cases. The possibility of a virus infection in this case was considered. Preoperative bacteriologic tests or antiseptic treatments are not mentioned in the case histories. (References.) K. W. Ascher.

Sen, K. **Anterior lentiglobus. An atypical case.** Brit. J. Ophth. 32:305-311, May, 1948.

Anterior lenticonus is a small conical projection of the lens at its anterior pole and anterior lentiglobus is a similar ir-

regularity that is globular. Both these conditions are extremely rare. It is confined to the anterior capsule and cortex only and the rest of the lens is unaffected. It has a tendency to increase and because of its high curvature produces myopia. Its cause is unknown.

Sen describes a 14-year-old Sikh who complained of sudden reduction in vision of one eye. Examination revealed a globular projection on the lens partly in the pupillary area and partly covered by iris. Vision was 5/60 and could be improved only by contraction of the pupil to 6/24. It measured 3 by 2 mm. and was egg-shaped. The capsule seemed to be entirely absent over it but this is unlikely because the cortex over it remained clear. The other eye was quite normal. (7 figures.) Morris Kaplan.

11

RETINA AND VITREOUS

Dor. **Retinal detachment cured by intravenous novocaine injection.** Ann. d'ocul. 181:300-301, May, 1948.

The retina was detached below in a 57 year old man who had noted progressive loss of sight for one month. A preliminary subconjunctival injection of cyanide-novocaine-dionin was followed by improvement. The retinal detachment was apparently due to a spastic lesion which was further reduced by an intravenous novocaine injection. Five months later vision was 0.5 and one year later the retinal detachment had not recurred.

Chas. A. Bahn.

Hambresin, L., and Schepens, C. **Retinal detachment operation with constant ophthalmoscopic control.** Ann. d'ocul. 181: 257-273, May, 1948.

This interesting contribution marks a step forward in retinal detachment surgery. The authors control the operation for retinal detachment by means of constant ophthalmoscopic examination, and externally by transillumination which is maintained throughout the operation. The binocular ophthalmoscope which is used by the indirect method is mounted on a stand. The combined pyrometric electrode and transilluminator can be sterilized and permits the use of both the right-angled and straight electrodes as well as two transilluminator tips from a common collar on the handle. The electric diathermy mechanism consists of two separate units one for transillumination, and the other for diathermic applications. They are insulated from each other and are regulated by separate foot controls. Before the operative procedure the fundus, including the detachment and tears, is diagrammed on the Weeve Chart which is about eight inches in diameter. A three-man team is necessary for this operation: the surgeon, his assistant and the ophthalmoscopic observer. The procedure consists of a series of superficial applications followed by several perforating applications of 8 to 10 seconds duration. The amount of current is individually determined. Air injections are used according to the Barraquer-Amsler technique. Chas. A. Bahn.

Lijó Pavía, J., and Lis, M. **Obliteration of the central retinal artery. Partial recuperation of vision and retinographic aspects.** Rev. oto-neuro-oftal. 22:97-104, Sept.-Dec., 1947.

In addition to embolus, thrombus, and local endarteritis as causative fractors in obliteration of the central retinal artery, angiospasm must be considered, and not necessarily in the elderly only. Two cases are reported in which there was sudden loss of unilateral vision and a diagnosis of occlusion of the central artery was made. The fundus picture was typical. Acetyl-choline and nicotinic acid, together with liquemine (an anticoagulant) were administered and some definite im-

provement of vision followed. (5 retinographs.) Edward Saskin.

Pascheff, C. **Angioid streaks of the retina as a transitory phenomenon.** Arch. d'opht. 8:152-155, 1948.

Pascheff reviews the various theories of the origin of angioid streaks and reports a case which he was able to follow for eight years. The patient, a woman of 32 years, did not have the commonly associated pseudoxanthoma elastica or diabetes but did have typical angioid streaks in both eyes and reduced vision. Seven years later the streaks had disappeared completely and vision had notably improved in each eye. In commenting on the case, the author describes the condition as a veritable melano-reticular retinitis and notes that both the vascular hypothesis and the hypothesis of rupture of the lamina vitrea are untenable in view of the result in this case. He considers a metabolic disorder the probable cause. In his patient the sole discoverable metabolic abnormality was a hypercholesteremia and this was still present after the disappearance of the streaks. Pascheff concludes that the streaks are probably an infiltration with pigment.

Phillips Thygeson.

Scuderi, G. **Exudative affections of the external layers of the retina of tuberculous nature. Part I.** Rassegna ital. d'ottal. 17:103-128, March-April, 1948.

Scuderi divides the rather rare and not too well understood affections of the external layers of the retina into two groups. The juvenile form includes Coats's disease, the macular juvenile form of Junius, and the central serous retinitis of Masuda. The senile group is composed of the disciform degeneration of Junius and Kuhnt, exudative senile macular retinitis, central chorioretinitis with arteriovenous anastomosis of Oeller, the fibrochondroma of the elastic layers, exudative retinitis with bone formation of Axenfeld, the tumor-like accumulation of tissue at the macula of Elschnig and the senile macular alterations of arteriosclerosis (Possek).

Radiographic examinations of the writer's patients disclosed alterations of the hilar lymph glands from which he believes that tubercle bacilli, or more probably their toxins, find their way into the circulation and, passing through the choriocapillaris to the epithelial pigment, give rise to an abnormal secretion.

Two cases are reported and the literature reviewed. (8 figures.)

Eugene M. Blake.

Vail, Derrick. **Some thoughts on the surgery of retinal detachment.** Wisconsin M.J. 47:687-689, July, 1948.

The essentials for success in the treatment of retinal detachment were recognized and clearly stated by Gonin. They are the finding of a tear, hole, or disinsertion of the retina, the exact localization of the hole, the production of adhesive choroiditis in the area of the hole and nowhere else, and the evacuation of the subretinal fluid. The penetrating needle should not be too long. The anaesthetic of choice is pentothal sodium. The cornea should be kept clear for frequent ophthalmoscopic examinations during the operation. Scleral resection should be done if a scleral staphyloma is the cause of the detachment. The ciliary region and the vortex veins should be avoided. The prognosis is poor when there are delayed hemorrhages, a severe postoperative reaction, bilateral spontaneous idiopathic retinal detachment and when the retina has not returned to its normal position and the pigmented scars of the ignipuncture are not easily visible at the end of three weeks.

I. E. Gaynon.

Winkelman, J. E. **Angioid streaks.** Ophthalmologica 115:84-88, Feb., 1948.

Winkelman reports the case of a white female patient, 72 years of age who died of heart failure. A conspicuous clinical

finding was the presence of multiple pseudoxanthomata elastica. Because of this finding, the patient's eye grounds were examined carefully just before her death, but no angioid streaks were found. Histological examination, however, revealed the typical pathological changes of Bruch's membrane (thickening, ruptures, abnormal staining reactions) which have been described by Böck (Zeitschr. f. Augenheilk. 95:1, 1938 and Hagedoorn (Arch. of Ophth. 21:746, 1939). These changes may therefore be present before the angioid streaks become ophthalmoscopically visible. Peter C. Kronfeld.

12

OPTIC NERVE AND CHIASM

Casanova, José. **Papilledema.** Arch. Soc. oftal. hispano-am. 8:221-290, March, 1948.

This extensive monograph comprises a thorough review of the literature, and a comprehensive bibliography, classified under the headings of symptomatology and diagnosis, pathologic anatomy, pathogenesis, clinical significance, and therapy. The original features of the monograph are two colored fundus drawings, and visual fields in a case of serous meningitis, and one of gumma of the occipital lobe; the histo-pathologic material used to illustrate the chapter on pathologic anatomy; and a report of Casanova's investigations with injections of China ink into the intervaginal space of a cadaver after doing an orbital exenteration. As the photomicrographs demonstrate, the ink is seen to distend the intervaginal spaces, but does not penetrate into the lymphatic spaces about the central retinal vessels, or extend through the perivascular spaces towards the dural surface.

NEURO-OPHTHALMOLOGY

Raski, K. **Concentric contraction of the visual fields in gunshot wound of the brain and in brain contusion.** Acta ophth. Suppl. 29, 1948, pp. 1-137.

Brain lesions caused by trauma either of lighter degree or severer cerebral contusion were followed by a concentric contraction of the visual fields. The region of the brain affected by the trauma had no direct influence on the concentric contraction of the visual field. The visual field for white was contracted in 78.4 percent and for color in 96.8 percent. The greatest contraction occurred for blue whereas the field for red was less affected. The visual field changes persisted and could be ascertained even after the lapse of several years. Psychogenic disturbances evidently had no effect on the result of the visual field changes. R. Grunfeld.

Rich, W. M. **Permanent homonymous quadrantanopia after migraine.** Brit. M. J. pp. 592-594, March 27, 1948.

Permanent quadrantanopia, in the patient's superior right visual fields, following twenty years of repeated attacks of idiopathic migraine is described. It is assumed that the defect results from permanent occlusion of the vessels, with softening of the brain tissue, after a long period of merely functional disorder, rather than the possibility that the friction from an ossified clinoid ligament damaged the optic tract. A review of the literature is given. (4 figures, references.)

Bennett W. Muir.

Smorto, Guido. **Some ocular reflexes in electroshock convulsion.** Riv. oto-neuro-oftal. 22: 272-291, July-Aug., 1947.

In 22 patients, 15 of them men, affected by schizophrenia, melancholia, or psychasthenia, the behavior of the reflex ocular movements in convulsion from electric shock was tested at the beginning of the tonic phase and during the comatose phase. In the tonic phase, when the epileptogenic stimulus slowly expands, an initial crossed rotation of the head and the eyes was noted. This is a tonic reflex

originating in the deep receptors of the neck. During the comatose phase compensatory ocular movements were noted which the author relates to stimuli originating in the nonacoustic labyrinth.

Melchiore Lombardo.

Wagner, H. P. **Visual hallucinations.** Am. J. M. Sc. 215:226-232, Feb., 1948.

Visual hallucinations are not due to local cortical excitability but are psychic phenomena involving the total integrative activities of the mind. Visual memory and visual experience are necessary for visual hallucinations, as it is well known that congenitally blind children do not have visual hallucinations. As to the localizing value of visual hallucinations, much data has been collected, and a careful study reveals that there is none, except that when the hallucinations are projected in a blind homonymous field it is a confirmatory sign that the lesion is located in the contralateral hemisphere. Many clinicians believe, however, that complex lateral visual hallucinations furnish supportive evidence that the lesion is in the temporal lobe, and unformed ones originate in lesions of the occipital lobe.

Orwyn H. Ellis.

Weekers, Roger. **Tonic pupillary reaction (Adie's syndrome) following retrobulbar alcohol injection.** Ann. d'ocul. 181: 193-198, April, 1948.

The retrobulbar injection of ethyl alcohol is not infrequently employed in Europe to relieve ocular pain, especially in blind eyes. Among the infrequent complications following its use is a transient extraocular muscular weakness and the more permanent tonic pupillary reaction (Adie's syndrome). Four cases of the latter are reported. The semidilated pupil in the second stage reacts imperfectly with accommodation and convergence, and does not react at all to light. Myosis is promptly produced by cholinergic drugs that are stable derivatives of acetylcholine, but not to cholinergic drugs that inhibit or destroy cholinase. The former group includes acetylbetamethylcholine (mecholin), the latter, eserine and D.F.P. which have no myotic effect. Adrenergic drugs such as adrenalin produce only slightly increased dilatation which proves that the sympathetic mechanism is not involved.

EYEBALL, ORBIT, SINUSES

Babel, J. **Chronic orbital myositis.** Ophthalmologica 114:312-319, Oct.-Nov., 1947.

The clinical symptoms of chronic orbital myositis are: (1) slowly progressive, painless, irreducible exophthalmos without lateral or vertical displacement of the eyeball; (2) lid edema, often associated with ptosis and chemosis, and always associated with dilation of the conjunctival vessels; (3) limitation of active ocular movements in all directions, and (4) limitation of passive ocular movements (Dunnington and Berke, Arch. of Ophth. 30: 446, 1943). These four symptoms do not always permit the differentiation of chronic myositis from true orbital tumors, inflammatory pseudotumors and orbital diseases due to endocrine disturbances. With very rare exceptions, chronic orbital myositis is a disease confined entirely to the orbit (or in one-fourth of the cases to both orbits), without involvement of any extraorbital muscles, without any signs of thyroid or pituitary dysfunction, without any blood dyscrasia and without any circulatory disease (other than arteriosclerosis in elderly patients). Keeping all these possibilities in mind, the diagnosis on the basis of the clinical findings may be so uncertain that orbital exploration and biopsy are resorted to. The author describes a case in which the presence of an orbital tumor was suspected. Exploration

of the orbit revealed fibrosis, an abundance of dilated blood vessels and, posteriorly, a hard mass, pieces of which were removed. Histologic study disclosed a diffuse, inflammatory process which was much more pronounced in the muscles than in the interstitial fatty tissue. The author believes that the characteristic difference between chronic myositis and inflammatory pseudotumors is the specific involvement of the orbital veins in the former disease. More thorough clinical investigation of the circulatory disturbance may permit recognition of chronic myositis. Another clinical clue may be a limitation of ocular movements out of proportion to the degree of exophthalmos.

Peter C. Kronfeld.

Cibis, P. **A new plastic implant made of "Supramid" for sockets after enucleation.** Klin. Monatsbl. f. Augenh. 112:313-316, 1947.

A plastic ball implant is described which has a central tubular hole which penetrates almost its whole diameter. Plastic sutures or catgut are threaded into this tubular cylinder through two small openings at the base and leave it at the opposite side. After the implant is in place, the sutures are threaded through the four rectus muscles and through Tenon's capsule in the usual circular fashion. Firm connection between implant and overlying muscle is thereby established and leads to good movements of the base of the socket and the prothesis. The recently developed implants by American authors are not mentioned. (References.)

Max Hirschfelder.

Devoe, A. G. **Fractures of the orbital floor.** Tr. Am. Ophth. Soc. 45:502-526, 1947.

Thirty-four cases of fracture of the orbital floor were observed. The immediate care of such fractures will rarely be an ophthalmological problem because of the multiplicity of injuries, often of a vital nature, which usually accompany the condition. Immediate treatment is reviewed. Late treatment which may take the form of operation on the extraocular muscles or substitution of inert material in the orbital floor is in the province of the ophthalmologist. Restoration of the orbital floor may improve the cosmetic appearance.

David O. Harrington.

Doctor, L., and Kennedy, R. J. **Tumors of the orbit.** Cleveland Cl. Quart. 15:99-103, April 1948.

A brief review of the clinical manifestations and incidence of orbital tumors is given. The measurement of exophthalmos with a forward displacement over 20 mm. is the most consistent finding. The use of additional diagnostic methods and the differential diagnosis is discussed. The treatment varies with the final diagnosis. Operation should be performed when visual acuity becomes endangered.

A neurilemmoma in a woman 50 years of age is reported with the description of the tumor; a lymphosarcoma in a 65-year-old man (a tumor which involves muscle as well as the eyeball) is described and finally a report of an adenocarcinoma of lacrimal gland which is cylindroma in type is given. (1 figure.)

H. C. Weinberg.

Favory, Albert. **Some new points in the technique of implant in Tenon's capsule after enucleation.** Brit. J. Ophth. 32:366-372, June, 1948.

The author presents an acrylic implant for use after enucleation. The implant is essentially a ball, 10 mm. in diameter, with four arches for the attachment of the rectus muscles and a square projecting peg. Tenon's capsule and the conjunctiva cover all but the peg which finally is fitted into a square hole in the back of the specially made prosthesis. In a further modification the projecting arches were re-

placed by a disc which had four kidney-shaped holes for the attachment of the rectus muscles. Silk is used in suturing the muscles and this, after being passed a second time through the muscle tendon, is passed out through the conjunctiva and tied. Good results followed two early failures. Orwyn H. Ellis.

Fischer-Galati. **Myositis and subacute orbital cellulitis.** Ann. d'ocul. 181:302-303, May, 1948.

A previous contribution is briefly discussed and the following case is presented. A 64-year-old man complained of pain and decreased vision that had followed the feeling of a foreign body in his left eye. Only slight conjunctival injection was found. Three days later a progressive monocular exophthalmus developed. Improvement began after the use of penicillin and treatment of the diseased maxillary sinus. Chas. A. Bahn.

Gát, L. **The plastic repair of symblepharon.** Ophthalmologica 114:414-418, Dec., 1947.

The original title of this paper is "on partial plasty of the socket." Actually it deals with the plastic repair, by means of mucous membrane grafts from the mouth, of posterior or total symblepharon in the presence of a seeing eye. In posterior symblepharon in which there is enough bulbar conjunctiva to line the fornix the tarsal conjunctiva is incised parallel to and close to the lid border and undermined toward the bony orbital margin. Thus enough conjunctiva becomes available to form a fornix. The resultant defect of tarsal conjunctiva is filled in with mucous membrane. In total symblepharon the scar tissue is completely removed and both walls of the resultant cavity are lined with *one* mucous membrane graft wrapped around a thin piece of properly shaped plastic or stent composition.

Grignolo, Antonio. **Results of penicillin treatment in ocular complications of septic thrombophlebitis of the cavernous sinus, with particular consideration of a case complicated by bilateral occlusion of the central retinal arteries.** Boll. d'ocul. 26:749-763, Dec., 1947.

In spite of the early administration of penicillin in large doses the patient, a man 38 years of age, developed bilateral occlusion of his central retinal arteries on the fifteenth day of his disease. This rare complication is extensively discussed. (Bibliography.) K. W. Ascher.

Hickman, W. R., **Periorbital cellulitis; a report of four cases.** J. Indiana St. M.A. 41:501-504, May, 1948.

Periorbital cellulitis is uncommon and in children and young adults is secondary to sinusitis. Findings are edema and redness of both lids on the affected side, pain in and over the affected eye, elevated temperature and generalized headache. The combined use of sulfamines and penicillin is most effective. Pus must be evacuated. Irwin E. Gaynon.

Hughes, W. L. **Further experiences with integrated eyes and vitallium implants.** Am. J. Ophth. 31:854-860, July, 1948. (3 figures, 5 references.)

Kniper, A. **Roentgentherapy of an orbital pseudotumor.** Boll. d' ocul. 26:719-723, Nov., 1947.

Pseudotumors of inflammatory character are recognized by long duration and recurrent deteriorations. Surgical intervention is not advisable because of the good effect following irradiation. (1 photomicrograph, bibliography.)

K. W. Ascher.

Lederer, J. **Folliculine in some cases of thyroid exophthalmus.** Ann. d'ocul. 180: 37-45, Jan., 1948.

Exophthalmus decreased after follicu-

line administration in five patients. All patients were women in the fourth decade whose ovarian functions had been eliminated surgically or because of the climacteric. In each case the exophthalmus followed decreased ovarian function, varied from 2 to 7 mm., and was binocular. Folliculine administration is indicated in the thyrotropic form accompanied by defective ovarian function. This form is apparently due to imbalance of the diencephalic mechanism which coordinates individual glandular activities into patterns of vasomotor function. Endocrine exophthalmus in one sense is a glaucoma in the orbit. The retained fluid produces degenerative changes in the orbital tissues. Chas. A. Bahn.

Montresor, Dante. **Orbital inflammation treated with penicillin.** Ann. di ottal. e clin. ocul. 73:92-96, Feb., 1947.

Treatment with sulfonamides of a 36-year-old man with an infiltrative phlegmon of the left orbit and signs of cavernous sinus thrombophlebitis had been ineffective and had caused anemia. The response to penicillin was prompt and rapid, and complete recovery resulted.

Cassady, J. V. **Dacryocystitis of infancy.** Am. J. Ophth. 31:773-780, July, 1948. (7 figures.)

Cockrum, W. M., Slaughter, H. C., Lynch, H. D., and Austin, E. W. **Styes: the role of nutrition in etiology and treatment.** J. Indiana St. M.A. 41:489-491, May, 1948.

The authors found that styes occur in children who are on a low protein-high carbohydrate diet, regardless of their economic state. A well-balanced protein intake, with minerals and vitamins is most important, whereas local treatment, refraction and search for foci are procedures of secondary importance.

Irwin E. Gaynon.

Couzi, J. **Staphylococcal blepharitis.** Ann. d'ocul. 181:274-292, May, 1948.

In a series of 48 patients with blepharitis it was shown by accepted laboratory methods that the staphylococcus was the cause in 46. This same ratio has been previously verified. An anatomical classification is preferred. Cutaneous lesions may be eczema, impetigo, herpes, psoriasis, pemphigus, or the lesion may be predominantly glandular or ciliofollicular. The allergic or hypersensitive factor is manifested by a quantitative and qualitative disproportion of effect and cause. The number of potential allergens is tremendous. Tissue hypersensitivity may be local, as determined by intradermal tests, or bodily, as determined by tests such as that of Pausnitz-Kustner or by eosinophilic increase. Refractive errors may aggravate blepharitis because both have photophobia. Its reduction with correcting lenses potentially reduces blepharospasm through improved marginal venous circulation.

The author concludes that most of the eye drops, washes and compresses frequently used in the treatment of blepharitis retard rather than hasten recovery. Much more important are the expression of abnormal secretion from the oil glands, the removal of diseased lashes and crusts, and the avoidance of physical or chemical irritation. Penicillin and sulphonamides are the most effective remedies. The latter has been found the less efficacious. Resistance to penicillin is not infrequent and may occur immediately or after a time. The local or extraocular use of both drugs singly or together may be advisable and 2,500 units of penicillin combined with a sulpha compound, cod liver oil, vaseline and lanolin is preferred

for local use. In the general desensitization of these patients regulation of their way of life is of primary importance. Hemo- and autoserotherapy have sometimes been followed by improvement. More efficient are autovaccines injected into the lids. Stock vaccines have not been found satisfactory.

Chas. A. Bahn.

Dupertuis, S. M. **Eyelid reconstruction in the blinded.** Plast. and Reconstruct. Surg. 3:269-282, May, 1948.

A series of ten war casualties is utilized to illustrate various principles and procedures used in the reconstruction of the eyelids of anophthalmic sockets.

Twenty-eight photographs and four excellent plates of surgical diagrams in sequence illustrate the article.

Alston Callahan.

Espildora Luque, C., Mosser, J., and Gormaz, A. **Sjögren's syndrome.** Arch. Soc. oftal. hispano-am. 8:333-350, April, 1948.

A review of the literature is followed by a brief report of nine cases. In none of these was there any demonstrable anatomic change or hypertrophy of the lacrimal glands. One patient related that the disturbance set in with swelling of the salivary, parotid, and submaxillary glands, and an annoyance in the upper lids which was probably caused by a swelling of the lacrimal glands. When first seen these swellings had disappeared and there was marked atrophy of the parotid glands. Another patient with marked gross hypertrophy of the parotid actually had a pseudohypertrophy, and as shown photomicrographically, the glandular elements were replaced by fibrous tissue. Mosser devised a quantitative test for the dryness of the mouth, similar in principle to Schirmer's test. He placed the filter paper at angles of the mouth. All nine patients suffered to some extent from arthritis, the symptoms of which preceded symptoms of Sjögren's syndrome. Three patients who had gastric analysis were found to have achylia and hypochlorhydria. Since it is generally believed that Sjögren's syndrome is a disease of the menopause, it is worthy of note that one of the patients became affected at the age of eleven years and one at 26. An unusual history is that of the patient in whom the disease set in at the age of 33 years with an acute attack of dryness of the lids, mouth, and throat after an electric shock. Cauterization of the lacrimal puncta with a thermocautery is recommended as the most effective means of alleviating the ocular discomfort. Vitamin therapy is used with variable and uncertain results. (7 figures.)

Hirschfelder, M. and Frost, J. **Carcinoma of the inner canthus and forehead.** Am. J. Ophth. 31:999-1001, Aug., 1948. (2 figures.)

Jorio, S. **Concerning blepharoplastic surgery.** Rassegna ital. d'ottal. 17:85-103, March-April, 1948.

After a historical review of plastic surgery of the eyelids Jorio describes in detail and illustrates with pictures the method he used in a variety of deformities. Some were corrected with sliding flaps, some by torsion flaps and others with Wolfe grafts. Grafts were removed from the postauricular region or from the inner surface of the arm.

Many years of experience in lid surgery have lead the author to the conclusion that patients are often late and distrust-

ful in seeking surgical relief, but that good functional and cosmetic results may be obtained if the procedure is not postponed too long. (27 figures.)

Eugene M. Blake.

Kettesy, A. **On genesis and operation of senile entropion.** Brit. J. Ophth. 32: 311-313, May, 1948.

Senile or spastic entropion is a simple turning in of the unchanged tarsus of the lower lid. Normally, the lid is held in proper position by two forces: the tarso-orbital fascia and the equally distributed tension of the orbicularis muscle.

The latter plays the much more important role and its normal distribution is maintained by connective tissue which branches between the bundles. In senility there is a slackening of this connective tissue so that the orbicularis becomes a single bundle near the margin of the lid and the disturbance of the distribution of pressure results in entropion. Remedial measures which do not repair this cause can only result in recurrence or, if overdone, in ectropion.

The solution of the problem is excision of the orbicularis muscle, nothing further. Under local anesthesia, with a lid plate in the lower fornix, a skin incision is made immediately below the lashes and the skin is undermined down to the orbital margin. The palpebral part of the muscle as well as the lower portion is thoroughly extirpated until tarsus and orbital fascia are exposed. Sutures are unnecessary as coaptation is perfect. The results are immediate and lasting and lid action remains perfectly normal. Removal of skin is never done and over-correction is not possible.

Morris Kaplan.

Kurz, O. **Unusual causes of blockage of the lacrimal passages.** Ophthalmologica 115:101-109, Feb., 1948.

A chalazion had perforated into the lower canaliculus. After incision and careful curettage of the chalazion by the conjunctival approach the canaliculus was sutured. The final result was excellent (no lacrimal fistula, no tearing).

In a second patient there was eversion of the lower punctum by a small tumor located on the conjunctival surface just below the border of the lid. Excision of the tumor augmented by the excision of a rhombic piece of tarsus and conjunctiva just below the tumor corrected the eversion of the punctum and the epiphora. The tumor consisted of lymphoid tissue.

Elongation and kinking of a lower canaliculus, probably after trauma (incomplete rupture) was corrected by plastic repair in a third patient.

Peter C. Kronfeld.

Malatesta, C. **Width of the lid fissure and length of the lacrimal canaliculi.** Boll. d'ocul. 27:88-97, Feb., 1948.

In 1916, Van der Hoeve described a congenital anomaly consisting of a reduction in length of the lid fissure, internal ankyloblepharon, a wide nasal base, enlargement of the lacrimal caruncle, and elongation of the lower lacrimal canaliculi. Similar but not identical cases were reported by Halbertsma (1929), Gualdi (1930), Leonardi (1931), Tirelli (1932), and Waardenburg (1933). Three cases are described, photographed, and the exact measurements reported in a table; the main findings are congenital ptosis, epicanthus, reduction in width and in length of the lid fissure, fusion of the lids at their internal extremities, increased distance of the nasal canthi from each other with normal interpupillary distance, and elongation of the lacrimal canaliculi. TUMORS

Anastasi, Giovanni. **On the histogenesis of the limbal epithelioma.** Ann. di ottal. e clin. ocul. 73:65-82, Feb., 1947.

Anastasi presents nine cases of epithelial neoplasm of the limbus in ascending order of their supposed histogenesis: a simple tyloma, an atypical tyloma, a simple papilloma, a papilloma in an early stage of transformation into a basal cell epithelioma, a papilloma undergoing transformation into a prickle cell epithelioma, a mixed papillomatous epithelioma, with proliferation of both the prickle cell layer and the basal cell layer, a prickle cell epithelioma, an invasive (terebrant) prickle cell epithelioma, and a basal cell epithelioma.

Contrary to Poleff, whose histogenetic scheme posits the existence of an "initial epithelioma," Anastasi considers that the histogenesis of limbal tumors can be explained on the basis of our knowledge of tumors in general. They are characterized by a gradual increase in alteration of the cells, which become more and more atypical as they go from precancerous forms (in tyloma and papilloma) to the truly cancerous prickle cell and basal cell forms. The differential diagnosis is not always possible clinically but is easily made histologically. The proper treatment is still surgical, though X-ray and radium therapy may be used as adjuncts. (25 figures, including 18 photomicrographs.)

Harry K. Messenger.

Calhoun, F. P., Jr. **Pigmented lesions of the eye and adnexae.** J. Med. Assn. Georgia 37:140-141, April, 1948.

Various pigmented conditions that involve the conjunctiva, lid, and uveal tract are briefly discussed. In early life the appearance of an area of pigmentation in the conjunctiva, or an increase in its size, may not connote serious trouble but in the adult these changes may be signs of danger. Rational therapy can be employed only after proper histologic study of the lesion, and complete local excision for this purpose where possible is recommended.

Bennett W. Muir.

D'Aquila de Castañe Decoud, A. **Histopathology of ocular gliomas.** An. argent. de oftal. 8:41-45, April-May-June, 1947.

Histogenetically, nervous tumors manifest themselves as astrocytomas, oligodendrogliomas, and other forms, whereas gliomas are either glial or nervous. The author presents the Bailey-Cushing histo-evolutionary classification of gliomas as opposed to the Hortega classification. Both these groupings, however, make use of the glial or neuroepithelial origin of the neoplasms. In the cases presented, the author feels that embryologically the undifferentiated type of retinal glioma is extremely malignant, whereas the optic nerve type of glioma has a much slower growth without metastasis (sic). Histologically, glio-epithelial perivascular pseudo-rosettes were commonly found and true rosettes were found in but one case. (8 figures, 1 table, references.)

Edward Saskin.

Dellaporta, A. **A case of bilateral malignant lymphomatous infiltration (lymphosarcoma?) of the lids of a four-year-old boy.** Proc. Ophth. Soc. Vienna. p. 85, Oct. 23, 1944.

One week after small-pox vaccination a sudden indolent swelling of the lids appeared in a four-year-old boy. In the beginning it was present only during the night and disappeared almost completely during the day time. The skin and conjunctiva were not involved. Beneath the skin, inside the orbital rims, pea-sized globular masses could be felt in the orbital tissue behind the skin-muscle layer of the lids. Very small retro-auricular glands were palpable. Blood count and the bone marrow obtained by sternal puncture were normal. Biopsy of one of the nodules revealed malignant lymphomatous tissue, possibly lymphosarcoma. The child died a few months later. F. Nelson.

Dunnington, J. H. **Granular cell myoblastoma of the orbit.** Tr. Am. Ophth. Soc. 45:93-101, 1947.

Granular cell myoblastoma is a relatively common tumor found in different locations throughout the body. Its occurrence in the orbit is rare. Two tumors are reported that arose in the orbit, one of which was malignant. There is no characteristic clinical picture and the differential diagnosis is purely a histologic one. In spite of a considerable literature on the subject there is still much confusion in terminology.

David O. Harrington.

Edgerton, A. E. **Chloroma: report of a case and a review of the literature.** Tr. Am. Ophth. Soc. 45:376-414, 1947.

This very complete review of the subject of chloroma presents the clinical and pathological picture of the disease, lists 366 cases collected from the literature and reports one new case in great clinical and pathologic detail.

David O. Harrington.

Hutchinson, B. B. **Management of intra-ocular foreign bodies.** Texas St. J. Med. 44:48-51, May, 1948.

Intraocular foreign bodies must be demonstrated by direct observation and X-ray if possible. A penetrating wound in the avascular portion of the globe with subconjunctival hemorrhage is indicative of a double perforation. The Sweet method of localization is most accurate. Anterior chamber foreign bodies may be removed through keratome incision at an angle of 45 degrees. Nonmagnetic foreign bodies in the lens may be allowed to remain in situ. Posterior segment foreign bodies should be removed through a scleral incision, followed by a diathermy barrage about the wound.

Levitt, J. M. **Malignant melanoma of the iris.** Am. J. Ophth. 31:863-864, July, 1948. (1 figure.)

Matteucci, P. **The melanogenesis of uveal sarcomas. On the oxidation of tyrosine and 3,4-dioxyphenylalanine in melanotic uveal tumors and in the normal human uvea.** Ann. di ottal. e clin. ocul. 73:183-186, March, 1947.

Tyrosine and 3,4-dioxyphenylalanine are readily oxidized when introduced into a preparation of neoplastic tissue obtained from melanotic sarcomas of the choroid, whereas their addition to preparations of normal human uveal tissue has no effect on the consumption of oxygen. In the case of normal choroidal tissue the results of this study accord with those of other investigators, but the data referring to tumor tissue are entirely new. Matteucci's experiments seem to confirm the hypothesis that the tumor pigment melanin has its origin in the neoplastic cells themselves. Harry K. Messenger.

Radnót, M. **Flat sarcoma of choroid.** Ophthalmologica 114:409-414, Dec., 1947.

There were two cases of "flat sarcoma" of the choroid among the 53 eyes with uveal sarcoma enucleated and examined

histologically at Imre's clinic in Budapest during 1940 to 1943. Because of its extensive contact with ciliary vessels and nerves the flat sarcoma invades and perforates the sclera earlier and in more places than the circumscribed inward-growing sarcoma. Peter C. Kronfeld.

Schmid, M. **Local recurrence of a melanosarcoma of the iris after extirpation of the tumor.** Proc. Ophth. Soc. Vienna. p. 82, Oct. 23, 1944.

A triangular pigmented tumor in the lower half of the right iris of a 40-year-old woman, extending from the chamber angle toward the pupillary margin and touching the posterior surface of the cornea was excised thoroughly. Apparently healthy tissue of the adjacent sector of the ciliary body was included. Histologic examination revealed a melanosarcoma. After three years recurrence in the sclera near the operative scar and nevoid pigmentations in the nasal section of the iris were found. Histologic examination of the enucleated globe revealed an infiltrating growth of pigmented spindle cells and confirmed the diagnosis.

F. Nelson.

Schulz, M. D., and Heath, P. **Lymphoma of the conjunctiva.** Radiology 50: 500-505, April, 1948.

The authors summarize the scanty reports both in the radiologic and ophthalmic literature on this rare condition. The cytology of the lesions is presented and classified. Treatment was successful in lymphoma limited to the conjunctiva, but in contrast to these, all patients whose conjunctival involvement was part of a generalized condition were dead in less than two years, or had uncontrolled disease. Orwyn H. Ellis.

Vrabec, F. **Melanoblastoma of the human choroid cultured in vitro.** Ophthalmologica 115:129-140, March, 1948.

With Carrel's method of tissue culture Vrabec obtained good in vitro growth from four cases of malignant melanoma of the choroid. P. C. Kronfeld.

17
INJURIES

Grant, W. M. **Ocular injury due to sulfur dioxide.** Arch. Ophth. 38:755-761, Dec., 1947.

Ocular injuries result from spraying of liquid sulfur dioxide and oil into eyes in refrigeration accidents. Four such cases are described in detail. The injuries were characterized by immediate damage to the corneal epithelium, as in acid burns, with underlying stromal and endothelial injury as in alkali burns. There is an early absence of severe pain, due apparently to a temporary anesthesia. In mild injury the outcome was complete recovery, while in severe damage dense opacification followed corneal infiltration and interstitial vascularization. John C. Long.

Leon Gangoso, Martin. **Traumatic aphakia and aniridia.** Arch. Soc. oftal. hispano-am. 8:402-403.

A 19-year-old food handler sustained a blow on the left eye, which perforated the globe and led to a complete loss of the iris and lens, and an intraocular hemorrhage. The intraocular blood gradually became absorbed and the eye recovered with a visual acuity of two-thirds, with a +9.00D. lens. The question of estimating the visual disability for legal purposes is raised, inasmuch as there is no binocular vision with unilateral aphakia but if his good eye were injured a unilateral visual acuity of two-thirds would permit him to continue his occupation. Ray K. Daily.

Marucci, Luigi. **A simple apparatus for outlining directly on the X-ray film information for the localization of intraocular metallic foreign bodies by the**

method of Comberg Borsotti. Giorn. ital di oftal. 1:36-46, Jan.-Feb., 1948.

The author briefly reviews the Comberg-Borsotti method of localization of intraocular foreign bodies and describes the Dufour technique. In the latter one uses the ring of Goldman and Bangerter, exposes two films, one anteroposterior and the other lateral and uses a transparent screen for outlining directly on the film the position of the foreign body. He then describes an original apparatus which allows direct reading of the position of the foreign body, both in the antero-posterior and the lateral view. The two schematic representations of Dufour are retained but one needs neither geometry nor drawing instruments.

Francis P. Guida.

Wall, Walton. **Acute tetanus following a perforating injury of the eye.** Eye, Ear, Nose and Throat Monthly. 27:179-182, April, 1948.

The author reports an interesting case of acute tetanus that occurred five days after a perforating ocular injury. Although the incubation period was probably prolonged by its use, penicillin did not seem to affect the clinical course of the disease. The patient responded to antitoxin. In reported cases the mortality for this condition is high.

SYSTEMIC DISEASE AND PARASITES

Anderson, W. B., Nicholson, W. M., and Iverson, L. **Temporal arteritis with associated optic atrophy.** South. M. J. 41: 426-434, May, 1948.

Two case reports are given of temporal arteritis with optic atrophy caused by occlusion of the central retinal artery. Ocular signs occur in about one-third of the reported cases. The pain of the arteritis seems to be helped by section of the vessels for histologic study. The etiology is entirely obscure. (Bibliography, 8 figures.)

Bennett W. Muir.

Bansi, H. W. **The pathological physiology of undernourishment and deficiency diseases.** Klin. Monatsbl. f. Augenh. 112: 289-299, 1947.

This article was written for the postgraduate education of German specialists, particularly oculists, who in the Europe of today are in close contact with various stages of undernourishment. It discusses metabolic happenings during qualitatively and quantitatively deficient protein intake, the disturbed metabolism of nitrogen and oxygen and the various vitamin deficiencies. One finds disturbances in the field of enzymes and hormones, hypothyroidism, hunger edemas and pathological behavior of the liver function.

Max Hirschfelder.

Böck, J. **Subretinal cysticercus.** Proc. Ophth. Soc. Vienna p. 89, Dec. 11, 1944.

In the macular region of the retina of a man, 48 years of age, a round bullous lesion was found about 1.5 disc diameters in size. At its lower border hemorrhages and white spots were seen. The disc was blurred and somewhat prominent. The vitreous body was opaque and detached posteriorly. Four weeks after the first examination the focus had doubled in diameter and the worm could be observed moving inside the cyst. Cysticercus reaction was positive in the blood. After temporary detachment of the external rectus and the inferior oblique muscles the sclera was incised with guidance of the localizing method of Weve-Lindner by transillumination. After incision no choroidal tissue was seen and no hemorrhage occurred probably because the choroid had been changed by the presence of the cysticercus. The cyst could be removed in toto. Resulting vision was 2/60. The cysticercus reaction in the serum be-

came negative within a few weeks and remained negative. F. Nelson.

Brinkhorst, C. D. **Toxoplasmosis.** Ophthalmologica 115:65-77, Feb., 1948.

The author reports a case of a six-year-old girl with characteristic symptoms of toxoplasmosis, namely psychomotor disturbances, microcephaly, microphthalmos and chorioretinitis. The clinical diagnosis was confirmed by the demonstration of toxoplasma-like parasites in animals inoculated with the patient's spinal fluid. "This is the first case known in the European literature, in which the diagnosis was made intra vitam, and it is one of the few non-fatal cases of infantile toxoplasmosis described." The author also reports three other, less conclusive, cases and reviews the literature.

Peter C. Kronfeld.

Bruce, G. M. **The ocular fundus in pheochromocytoma of the adrenal gland. Report of three cases.** Tr. Am. Ophth. Soc. 47:201-228, 1947.

Three cases of this condition in children, all showing retinal lesions are reported. The literature is reviewed with special reference to ocular pathology. The dominant finding in such cases is vascular hypertension, in the course of which pathologic conditions may be found in the retina, in its blood vessels, or in both. The findings cannot be differentiated ophthalmoscopically from those of essential hypertension. Sooner or later failure of vision will bring the ophthalmologist into consultation and the condition should be considered wherever evidence of vascular disease is found. David O. Harrington.

Brun, J. **Early and late tuberculosis, including paraglandular.** Ann. d'ocul. 181: 81-105, Feb., 1948.

In this outstanding contribution, 740 cases of ocular tuberculosis are analyzed according to their place in four categories.

Extraocular semiology. Primary infections before the age of 20 years are classed as youthful; after that age, adult. The initial signs of primary pulmonary-glandular infection are: recent exposure to contact; slight systemic toxemic reactions, not infrequently with local cutaneous and ocular phlyctenules; mediastinal adenopathy; strongly positive cuticular or other tuberculin reactions; positive tubercle inoculation from gastric contents. In the later stages of infantile and youthful infection, the more positive signs are persistent but apparently recent cervical and/or subclavicular adenopathy and recent idiopathic serofibrinous pleurisy. The less positive signs are enlarged pulmonary and/or subclavicular nodules, often fibrosed or calcified as determined radiologically, clinical symptoms of pleurisy, asthenia, loss of weight, fever, and transient involvement of the eyes, testicles, kidneys, and other organs. The early signs of primary pulmonary-glandular infection in adults and recurrences of primary infections in infancy and childhood are frequently similar. The more positive signs are persistent cervical or mediastinal adenopathy with or without suppuration, infiltrative lung lesions, recurrent or old, usually in the upper lobe, and various extrapulmonary lesions involving the eyes, especially deep keratitis and uveitis, viscera, skin and joints. The less positive signs include prolonged infectious contact, cervical or mediastinal calcified gland lesions radiologically determined, enlarged glands, especially apical and subclavicular, variable, but usually transient, local and serous reactions like pleurisy, synovitis, phlyctenulosis, deep keratitis, or uveitis, and strongly positive cuticular reactions, of greater importance in ages beyond 40 years. Recurrence of lesions is usually associated with increased immunity. The complete sequence of ocular involvements especially in youthful infections is phlyctenulosis,

deep keratitis or scleritis, uveitis, iritis, iridocyclitis, choroiditis.

Phlyctenular keratoconjunctivitis. 404 cases. This most frequent ocular manifestation of tuberculosis of which 404 cases were observed usually occurs before the age of 12 years and is essentially a local, serous, hypersensitive reaction. It occurs within one year of the primary infection in 80 percent of patients. In 94 percent of patients a strongly positive cuticular reaction usually develops several months before the onset of the phlyctenulosis which coexists with mediastinal adenopathy in 16 percent of the patients. There are recurrences in 50 percent which usually are accompanied by persistent strongly positive cuticular reactions. In 63 percent the history of tuberculous familial or parafamilial prolonged contact was obtained. Primary nasopharyngeal and tonsillar infection is especially frequent in the very young, with resulting early cervical adenitis. Phlyctenulosis may follow numerous infectious and metabolic diseases especially in children with or without an associated glandular tuberculosis. The most frequent sequel and complication of recurrent phlyctenulosis especially in youth is deep keratitis and scleritis which may be followed by uveitis. In adults phlyctenulosis is infrequent and usually there is coexistent mediastinal adenopathy.

Deep keratitis and scleritis. 138 cases. This group usually begins at a later age than phlyctenulosis, between the ages of 10 and 20 years in the younger group, and between 20 and 50 years in the older group. In younger persons these diseases follow primary infection by not less than six to nine months and often represent a sequel to one or more attacks of phlyctenulosis. They are also secondary to a persistent mediastinal and cervical adenopathy and in 15 percent were associated with pleurisy. In older persons they follow the primary infection usually by years and correspond somewhat to the early tertiary stages of syphilis. Familial and other probable sources of infection were reported in 50 percent and strongly positive cuticular reactions existed in 58 percent.

Uveitis. 198 cases. This group includes iritis, iridocyclitis, choroiditis, and retinal hemorrhages, singly or in combination. In the earlier stages of youthful infection, iritis, although the most frequent of the group, occurred in but 4 percent. Of the eight cases analyzed, extrapulmonary infectious processes existed in four and a strongly positive cuticular reaction in five. The usual sequences in youthful primary infection are phlyctenulosis, deep keratitis or scleritis, and uveitis. Of the 190 primary infections of adults, 152 were in the iris and other anterior uveal tissue. Uveal involvement in the older group usually began between the ages of 30 and 40 years. Evidences of past or present pleurisy existed in 25 percent of the iritis patients. Apical pulmonary nodules were observed in 40 percent. Collapse therapy was frequently followed by marked ocular improvement. The cuticular reaction was strongly positive in 52 percent. The respective ages, probable source of infection, extraocular evidences of tuberculosis, and cutaneous allergy are analyzed in detail for each uveal group.

Paraglandular ocular tuberclosis: In this section, the relationships of phlyctenulosis, deep keratitis, and scleritis, as well as the different forms of uveitis are analyzed from the standpoint of the pulmonary-glandular and other tuberculous processes such as mediastinal, apical, and cervical adenopathies, in their relationship to youthful and adult primary and secondary ocular involvements.

Therapeusis. The favorable ocular progress of tuberculous patients treated with calcium, gold salts, methylic antigen, and tuberculin, has frequently been so slight that one cannot but wonder

whether or not their use was justified. The treatment of enlarged tuberculous glands by radiotherapy is not new, but is now sufficiently understood to be more efficiently employed. Radiotherapy is contraindicated in very recent adenopathies, such as usually exist in early phlyctenulosis. It is indicated in the later stages and is without danger if employed with reasonable prudence. It reduces the infectiousness and toxicity of the glands through which most of the toxins reach the eye, but does not directly kill tubercle bacilli. Coincidental infections, especially staphylococcal and streptococcal, are not affected. Caseous glands should be evacuated before radiotherapy is begun. In cervical adenopathies, doses of 100 R are repeated every five days to form a series of five or six treatments. After a rest period of one month, the treatments may be repeated. Glandular retrogression usually begins within a month. The hygienic treatment of all tuberculous patients including those who have ocular involvements is the most important factor in tuberculous therapy. The author and most French writers on ocular tuberculosis insist upon the advantages of a high altitude, 4,500 feet or more above sea level. The successful treatment of ocular lesions is frequently complicated by secondary infections such as influenza and the infections of childhood. Ocular involvements usually signify tissue reactions to toxins transmitted to the eye through the lymph stream rather than hematogenous emboli. These lymphogenous toxins attack tissues which have been previously sensitized, injured, or which are constitutionally imperfect. Ocular involvements are therefore inversely proportionate quantitatively and qualitatively to pulmonary tuberculosis alone, because glandular infection and transmission is the dominant factor in ocular involvement.

The original article is but an abstract of a large monograph. Its thoroughness and understanding facilitate a better coordination of the clinical, pathological and etiological factors in the diagnosis and treatment of the ocular manifestations of tuberculosis. Chas. A. Bahn.

Goedbloed, J. **Capillary hemorrhages of the retina and capillary fragility.** Ophthalmologica 115:174-179, March, 1948.

One patient with hypertensive cardiovascular disease and one with diabetes showed small retinal hemorrhages associated with a high Goethlin index. Under treatment with rutin the Goethlin index returned to normal and most of the retinal hemorrhages disappeared.

P. C. Kronfeld.

Hartmann, E., Collin, P., and Vergne, P. **Scleroderma and fundus lesions.** Ann. d'ocul. 181:220-225, April, 1948.

Fundus lesions associated with scleroderma have until now not been recorded. Associated lens opacities, however, are not infrequent. In a woman, 57 years of age, with the classical structural and functional symptoms of generalized scleroderma, the following fundus picture was observed. Fifteen to 20 small gray-yellowish areas were irregularly arranged around the macula in both eyes. They were round or oval, and variable in size, averaging one-fourth disc diameter. Some were slightly pigmented, located in the deeper retinal layers and not associated with any vessels, and, in one eye, very faint deep radial lines were observed about the disc. Vision was normal as were the functions and structures of the orbit and its contents. The author apparently believes that the fundus condition is an unusual manifestation of the sclerodermal process which began in Bruch's membrane. The clinical picture suggests to me an atypical bilateral, progressive, presenile, perimacular, constitutional degenerative disease in a patient with another constitutional disease of the neuro-vascu-

lar type, scleroderma. Both have in common progressive mesodermal deterioration with imperfect repair. The differential diagnosis of the condition involves drusen as well as tapetoretinal, punctate, and vascular degenerative diseases of the retina. Chas. A. Bahn.

Hartmann, K. **Removal of a living cysticercus from the anterior chamber.** Klin. Monatsbl. f. Augenh. 112:333-338, 1947.

Cysticercus invasion of the bulbus has now become a rarity. Invasion of the anterior chamber is much more infrequent than localization in deeper parts of the eye. A case is described which presented the picture of a severe iridocyclitis. Only after repeated puncture of the anterior chamber and removal of the dense serofibrinous exudate was the cysticercus discovered as the cause of the inflammation. The parasite was alive and was removed in toto after keratome incision. The eye recovered. The life cycle of the taenia solium is described and the literature surveyed. (References.)

Max Hirschfelder.

Meneely, J. K. **Fever of undetermined etiology associated with bronchopneumonia, conjunctivitis, stomatitis, and adenopathy (Stevens-Johnson syndrome).** New York State J. Med. 48:1399-1400, June 15, 1948.

A febrile clinical complex of considerable severity and lesions in several systems of organs is described as seen in a 13-year-old girl. No causative organism was isolated. The author believes that his patient had a variant of the Stevens-Johnson syndrome. F. H. Haessler.

Much, V. **Eye findings after amebic dysentery and in ameba-carriers.** Ophthalmologica 114:384-396, Dec., 1947.

In Tel Aviv amebic dysentery with and without definite gastrointestinal symptoms is apparently a common disease. The diagnosis of the latter form is based on stool examinations for ameba, on stool cultures and on the complement fixation test. Because of the many borderline cases that are seen in Palestine, the ophthalmologist has been asked to be alert for eye manifestations of amebiasis. The most important and apparently quite common eye-symptom is a partial gray discoloration of the disc which ordinarily would be suggestive of multiple sclerosis. Observation of these patients over a period of several years reveals no signs of nervous system involvement nor any appreciable loss of visual function. An ocular manifestation of the impaired liver function in amebiasis is an abnormal increase in the permeability of the blood-aqueous barrier as evidenced by a more rapid passage into the anterior chamber of fluorescein taken by mouth than is characteristic of normal control individuals. Peter C. Kronfeld.

Németh, L. **Ocular changes in tuberculous skin diseases.** Ophthalmologica 115:167-173, March, 1948.

The eye findings in 36 patients suffering from various forms of tuberculosis of the skin are reported. Cicatricial ectropion, dacryocystitis and deep corneal scars were the more common manifestations of active or healed ocular tuberculosis. Eight patients showed involvement of the posterior segment in the form of choroiditis or chorioretinitis. The clinical picture and the course of the choroiditides varied a good deal. Striking are the noncharacteristic or even negative pulmonary findings. P. C. Kronfeld.

Redslob, E. **The problem of diabetic retinopathy.** Ann. d'ocul. 181:129-135, March, 1948; 181:224-243, April, 1948.

In some instances, insulin has apparently aggravated diabetic retinopathies. This may be due to impurities in the insulin, allergic reactions, or other factors. It is possible that in some persons insulin,

by increasing the fat content of the blood and tissues, may increase the tendency to lipid degeneration especially of the hemorrhagic type. Diabetic retinopathies are slightly more frequent since the use of insulin. It is therefore advisable to use the minimal dosage of insulin in patients who have rapidly progressive diabetic retinopathies, especially hemorrhagic. Diabetic retinopathies are less related to age than to the duration of the diabetic process. The amount of glycosuria and hyperglycemia is apparently not of major importance. The pathologic processes in diabetic retinopathies are not characteristic. The frequent, deep punctate hemorrhages, hyaline degeneration and circinate arrangement form a clinical picture which is not pathognomonic of diabetes. Arterial and arteriolar sclerosis is a frequently associated or a complicating condition. Ophthalmoscopically, the differential diagnosis may be difficult. The diabetic process may provoke atherosclerosis, hypertension and nephritis, especially intercapillary glomerulosclerosis. The last named apparently plays an important part in the progress of diabetic retinopathies. In compound diabetic and hypertensive retinopathies too rapid lowering of the blood sugar is not advisable because the blood sugar is usually inversely proportionate to the hypertension.

Chas. A. Bahn.

Ricca, Salvatore. **Two cases of solitary oriental button, of the prelacrimal region and on the lid.** Ann. di ottal. e clin ocul. 73:115-125, Feb., 1947.

Two cases of oriental button (cutaneous leishmaniasis) are reported. In one patient the chronic ulcerative granuloma was in front of the lacrimal sac and simulated a fistulizing peridacryocystitis; in the other the lesion was on the upper lid. In both cases the Leishmania tropica was found in smears. The differential diagnosis is discussed. In each case two local injections of emetine hydrochloride (2 cc. of 1 percent and 2 percent solutions, respectively, at four and six day intervals) brought about rapid recovery with excellent cosmetic results.

Harry K. Messenger.

Shannon, C. E. G., and Hunt, W. **The hyperophthalmopathy of Graves' disease.** Tr. Am. Ophth. Soc. 45:240-253, 1947.

Clinically hyperophthalmopathy is seen in the hyperthyroid, hypothryroid states and with a normally functioning thyroid and the type may vary in many ways. In the thyrotoxic state the exophthalmos is as much apparent as real, but it may be actual when the thyrotropic factor of the pituitary is excited.

Exophthalmos increases in 50 percent of cases after thyroidectomy. The pituitary secretion may sometimes be controlled by X-ray therapy. Where ocular symptoms are out of proportion to the thyrotoxicosis and in the presence of a low basal metabolic rate, thyroidectomy is contraindicated. The choice of treatment must be based on the morbid mechanism.

David O. Harrington.

19

CONGENITAL DEFORMITIES, HEREDITY

Biró, I. **Data concerning the heredity of astigmatism.** Ophthalmologica 115:156-166, March, 1948.

The author had the opportunity of examining 31 members of one family representing three generations. The transmission of astigmatism seemed to follow a somewhat irregular but, in principle, dominant pattern.

P. C. Kronfeld.

Franceschetti, A. **Embryopathy from German measles in pregnancy.** Ann. di ottal. e clin. ocul. 73:1-7, Jan., 1947.

Comment is made on three cases, in one of which there were numerous pigment spots of various sizes in the retina, espe-

cially at the posterior pole. To designate this fundus picture Franceschetti proposes the name of pseudo-retinitis pigmentosa. He also calls attention to a digito-ocular phenomenon, which he has observed in cases of congenital cataract and of amblyopia from microphthalmos and albinism, but which he has never met in cases where light perception is absent. The affected child spontaneously presses upon the eyes with the fingers and presumably produces phosphenes thereby. He has also noted an analogous digito-auricular phenomenon in one case. Illustrations are given of these phenomena, as well as of postrubeolic congenital cataract and of pseudo-retinitis pigmentosa. Harry K. Messenger.

Lloyd, R. F. **The clinical course of the eye complications of arachnodactylia.** Tran. Am. Ophth. Soc. 45:342-354, 1947.

It is generally thought that the lens dislocations and rigid irides seen in archnodactylia are nonprogressive congenital defects. Observations on 43 cases has convinced the author that many are true abiotrophies. While some patients complain only of reduced visual acuity, many have progressive lens dislocation and a degeneration that ends in detachment of the retina.

The hereditary pattern and clinical development of the disease and its eye complications is discussed. Operative hazards are reviewed. Five families and six individual cases are presented.

David O. Harrington.

Patrick, P. R. **Report of a survey of children born in 1941 with reference to congenital abnormalities arising from maternal rubella.** M. J. Australia. 1:421-425, April, 1948.

A severe outbreak of German measles occurred in Queensland in 1940 after which a large increase in the number of children admitted to the school for the blind and deaf occurred. Many of the affected children were examined and 7,822 returned questionnaires are analyzed. The most frequent abnormality found was deafness; then followed congenital heart disease, mental deficiency and cataract. A pigmentary abnormality in the fundus of these "rubella" children was noted, but their vision was unaffected. The problems of treatment, education, and prevention are discussed. Orwyn H. Ellis.

HYGIENE, SOCIOLOGY, EDUCATION, AND HISTORY

Bailliart, P. **What should we conceal from and what should we tell our patients?** Ann. d'ocul. 181:304-306, May, 1948.

Only moral honesty and professional responsibility can determine what should be concealed from the patient. Numerous illustrations are presented. Conditions which may be incurable today may tomorrow become remediable. Those who make positive statements should be doubly sure and realize the accompanying responsibility. Even a death sentence may be pronounced in a merciful manner. Those who are probably very soon to be sightless should be given the opportunity of adjusting themselves through Braille and other facilities for the sightless. The risks of operations should be thoroughly understood by the patient. Only too often patients are misled concerning the risks of operations. A difficult problem involves the time factor in the adjustment to blindness. Is it better for the patient to know the whole truth quickly in order that the adjustment may be more rapid, or should he be allowed to realize the truth more slowly so that he may have more time for adjustment? Chas. A. Bahn.

Clark, W. B. **Ocular onchocerciasis in Guatemala. An investigation of 1,215 natives infected with Onchocerca vol-**

vulus. Tr. Am. Ophth. Soc. 45:461-501, 1947.

The incidence of ocular onchocerciasis is still undetermined. Ocular manifestations were found in 44 percent of 1,215 patients with onchocerciasis or with a history of the disease and 0.43 percent of those with the ocular type of disease were blind or practically blind.

Unless the possibility of vitamin deficiencies, endocrine disturbances, focal infections, syphilis and tuberculosis are ruled out in persons with the disease all the ocular lesions found in patients with onchocerciasis cannot be attributed to the disease. Additional histopathologic studies are needed on the eyes of patients with onchocerciasis. The author considers that the characteristics of the fundal lesions suggest a degenerative rather than an inflammatory process. The possible methods of spread to the United States are discussed but this occurrence seems unlikely.

David O. Harrington.

Del Rio Cabana, J. L. **Appraisal of disability and compensation of industrial ocular injuries.** Arch. Soc. oftal hispano-am. 8:358-394, April, 1948.

At present the estimate of disability in ocular injuries in Spain is determined solely on the basis of visual acuity and is classified as temporary, partial permanent, total permanent, and absolute permanent. The loss of one eye, with one good eye remaining is defined as partial permanent disability. Disability is total permanent when one eye is lost and the other eye has less than a 50 percent impairment. Loss of one eye, with more than a 50 percent impairment in the other is classified as absolute permanent disability. Del Rio Cabana suggests a definite scale of compensation, similar to the one used in this country, based on loss of visual acuity, changes in the visual fields, disturbances in ocular motility, injury to the ocular adnexa, and factors which modify evaluation such as malingering or failure to use protective measures. The estimation of the impairment in these various functions is discussed in detail, and a compensation scale is presented. (6 figures.) Ray K. Daily.

Flowers, W. S. **Causes of blindness in China.** Chinese M. J. 66:38-46, Jan., 1948.

Blindness in China is caused by smallpox, trachoma, ophthalmia neonatorum, phlyctenular conjunctivitis, keratomalacia, ulcerative keratitis and muco-purulent conjunctivitis. Irwin E. Gaynon.

Gözcü, Niyazi. **Certain considerations on blindness in Turkey.** Göz Kliniği 6:1-5, 1948.

The positive results of the antitrachoma campaign which has been carried on in southern and southeastern Turkey since 1925 can be seen in a definite decrease of blindness rather than a decrease in the incidence of trachoma. The author compared the official statistical data of the trachoma campaign with those on blindness in the 1935 census. F. H. Haessler.

Imus, H. A. **Visual examination of flyers returned from combat.** J. Aviation Med. 19:62-93, April, 1948.

Two hundred and fifty naval aviators were given complete eye examinations upon their return from combat. The men who had been selected because of their superior visual capacity had retained it.

Irwin E. Gaynon.

Marisco, Vincenzo. **The battle against trachoma.** Boll. d'ocul. 26:710-715, Nov., 1947.

In the Lucania area of Italy, an apparent diminution of the number of trachomatous patients was due to the improvement that followed treatment with sulfa drugs. The number of infected families, and therefore the number of infectious foci, remained equal over the period 1940

to 1946. A comprehensive table shows the distribution of patients and of their complications.

K. W. Ascher.

Pereyra, Georgia. **The eyes of men of genius and historical personages.** Giorn. ital. di oftal. 1:73-83, Jan.-Feb., 1948.

This paper, read before the Lay Medical Society of Florence, discusses briefly the eyes and ocular affiictions of many well-known men of the past, starting with Homer and including Adolph Hitler.

Francis P. Guida.

Sorsby, A., and Bishop, W. H. **A portrait of Richard Banister.** Brit. J. Ophth. 32:362-366, June, 1948.

The authors present evidence to show that a certain painting in possession of the Royal College of Surgeons is really that of Richard Banister, one of England's early ophthalmologists. In his writings he gave the first account of hardness of the eye as a diagnostic and prognostic sign.

Orwyn H. Ellis.

Historical Miniatures

St. Yves gave the first satisfactory description of glaucoma in 1722. His predecessors could not bring themselves to discard the Hippocratic word "glaucosis," although this word was used by the ancients for any incurable clouding of the pupillary area. St. Yves, on the other hand, referred to glaucoma as one of the false cataracts and described a clinical picture of which pain, dilated pupil, loss of visual acuity and field, and finally loss of transparency of the lens were parts.

Hirschberg, *Graefe-Saemisch Handbuch.*

The diagrammatic cross section of the eye that appears in the famous *Anatomy* of Vesalius, published in 1543, makes it clear that even then the true position of the lens was not understood. The Hellenistic-Arabic conception of the tremendous depth of the anterior chamber is the basis for the then-current belief that the couching needle, after it had penetrated the cornea, entered a huge space in which it could move in great arcs in all directions without touching the lens.

Hirschberg, *Graefe-Saemisch Handbuch.*

News items should reach the editor by the 12th of the month

DEATHS

Dr. Roy M. Armstrong, Franklin, Kentucky, died May 3, 1948, aged 64 years.

Dr. Albert Stewart Barr, Ann Arbor, Michigan, died April 27, 1948, aged 65 years.

Dr. William Robert Morrison, Billings, Montana, died May 2, 1948, aged 72 years.

MISCELLANEOUS

ARMY RESIDENT TRAINING PROGRAM

A limited number of senior residencies in ophthalmology and a substantial number of assistant residencies in ophthalmology in Army general hospitals are available for newly commissioned officers under the military resident training program.

Under this program, any physician who qualifies for and accepts a commission in the Regular Army Medical Corps will be given the opportunity of competing for an approved residency in the field of his choice.

Applications for these residencies are currently being received in the Office of the Surgeon General.

HONOR SIR JOHN PARSONS

In honor of the 80th birthday of Sir John Parsons, his colleagues and friends presented to him his portrait painted by John Gilroy. The presentation was made on the afternoon of September 3rd in the library of the Royal College of Surgeons, Lincoln's Inn Fields, London.

FRANCIS I. PROCTOR LECTURE

On Friday evening, September 10, Dr. David G. Cogan of the Harvard University Medical School, Boston, delivered the third Francis I. Proctor Lecture on Ophthalmology at Toland Hall, University of California Medical School, San Francisco. The subject of Dr. Cogan's address was: "The Physio-Pathologic Basis for Some of the Signs and Symptoms of Corneal Disease."

ANISEIKONIC CLINIC

An aniseikonic clinic has recently been established in the eye department of the George Washington University Hospital, Washington, D.C. Facilities are available for the patient to have the frames measured and fitted in the hospital. The iseikonic lenses will be made according to prescription at the Southbridge plant of the American Optical Company. Dr. Ernest Sheppard, professor of ophthalmology, is the director of the clinic.

The patients are seen by appointment only. Arrangements for appointment can be made by writing to Miss Margaret W. Boudren, secretary, eye department, The George Washington University Hospital, 901 23rd Street, N.W., Washington 7, D.C.

WANTED: CASE REPORTS

If any ophthalmologist has had occasion to see a closure of the central retinal artery first recognized shortly after the patient came out of a general anesthetic will he be so kind as to convey the details of the case or cases observed to Dr. I. Givner, 108 East 66th Street, New York 21, New York. Please note which eye was affected, type of anesthesia used, length of the operation and its nature, whether or not the patient went into shock at the time of the operation, and if there were any evidences of the eye having been pressed upon during the anesthesia such as corneal abrasion, ecchymosis of the lids, and so forth.

DE SCHWEINITZ LECTURE

The 11th annual de Schweinitz Lecture sponsored by the Section of Ophthalmology of the College of Physicians of Philadelphia will be delivered by Dr. William L. Benedict on November 18th on the "Surgical Treatment of Tumors and Cysts of the Orbit."

UNIVERSITY OF GLASGOW LECTURES

During October a series of lectures are being given in the department of ophthalmology, University of Glasgow. The meetings, open to all medical practitioners and senior students interested in ophthalmology, are held at 8 o'clock each Wednesday evening. Tea is served after the paper and a discussion follows. On October 6th, Mr. Frank W. Law spoke on "Physiotherapy of the Eye." Dr. Paul Bacsich discussed "Experimental Corneal Grafting" on October 13th. "Plastic Surgery of the Eyelids" will be the subject presented by Dr. Byron Smith on October 20th, and Professor Loewenstein will speak on "Histopathology of the Drainage Angle" on October 27th.

SOCIETIES

WEST VIRGINIA MEETING

The fall meeting of the West Virginia Academy of Ophthalmology and Otolaryngology was held at the Greenbrier, White Sulphur Springs, September 20th and 21st. Dr. James A. Moore, New York, spoke on "Endaural Surgery in the Modified Radical and Radical Mastoidectomies," and Dr. Oscar B. Nugent, Chicago, on "Management of Strabismus."

ROUMANIAN SOCIETIES ORGANIZED

Word has been received that two new ophthalmic societies have been established in Roumania. The first of these is a clinical society, the Roumanian Society of Oculists, and is located at Timisoara.

Dr. Nicolas Blatt is president and Dr. Nicolas Zolog, secretary general.

The second, the Roumanian Society for the Prevention of Blindness, is also located at Timisoara. The president is Dr. Nicolas Blatt and the secretary general, Dr. Virgil Popovici.

Southern medical meeting

The ophthalmic program for the Section on Ophthalmology and Otolaryngology to be held in Miami at the annual meeting of the Southern Medical Association is:

Monday, October 25th

1. "Sympathetic Ophthalmia," Dr. Sam McPherson, Durham, North Carolina.
2. "Iridencleisis," Dr. E. G. Gill, Roanoke, Virginia.
3. "The Use of Erisophake in Cataract Extraction," Dr. E. R. Veirs, Temple, Texas.
4. "Keratitis Nummularis (Dimmer): A Report of Five Cases," Dr. Stacy Howell, Atlanta, Georgia, and Dr. Curtis Benton, Jr., Fort Lauderdale, Florida.
5. "Vertical Phorias," Dr. J. L. Berg, Albany, Georgia.

Wednesday, October 27th

1. "Selections of Operations for Glaucoma," Dr. Conrad Berens, New York.
2. Chairman's Address: "Malignant Melanoma of the Iris," Dr. Shaler Richardson, Jacksonville, Florida.
3. "The Management of Convergent Strabismus," Dr. Frank Costenbader, Washington, D.C.
4. "Cataract Surgery," Dr. Mason Baird, Atlanta, Georgia.
5. "Complications of Glaucoma Surgery," Dr. P. M. Lewis, Memphis, Tennessee.
6. "Sodium Pentothal in Elective Eye Surgery," Dr. William M. Boles, New Orleans, Louisiana.

Milwaukee meeting

The Milwaukee Oto-Ophthalmic Society held a joint luncheon meeting with the E.E.N.T. section of the Wisconsin State Medical Society on October 6th for its honorary members, Dr. Frederick A. Davis and Dr. A. D. Prangen. Dr. Davis presented a paper and motion picture on "Cataract Extraction."

Central Illinois society to meet

The next meeting of the Central Illinois Society of Ophthalmology and Otolaryngology will be held at the Abraham Lincoln Hotel, Springfield, Illinois, on November 13th and 14th.

Dr. F. Bruce Fralick, professor of ophthalmology, University of Michigan will speak on "Surgical Anatomy of Operations for Glaucoma," and will illustrate his lecture with moving pictures. Dr. Francis L. Lederer, professor of otolaryngology, University of Illinois, will discuss "Modern Approaches to the Prevention and Treatment of Defective Hearing." Dr. Roth, Belleville, Illinois, will present a paper on the "O'Connor Cinch Operation," and Dr. Judd, Kankakee, Illinois, will talk on "Malignancies of the Paranasal Sinuses."

Personals

Illinois faculty promotions

Dr. Georgiana D. Theobald has been promoted to associate professor of ophthalmology at the University of Illinois College of Medicine, and Dr. Joseph S. Haas has been given the rank of assistant professor of ophthalmology.

Attends Hawaiian meeting

Dr. Arthur J. Bedell, Albany, New York, attended the meeting of the Pan-Pacific Surgical Association in Honolulu, Hawaii, August 30th to September 13th, at which he presented a series of three lectures.

ERRATUM

The Journal regrets that in the paper, "Senile Macular Lesions," by Dr. Ralph I. Lloyd, appearing in the September, 1948, issue, credit was not given to Dr. Bonacolto for Figure 4 on page 1138 and to Dr. Dunnington for Figure 6 on page 1139.

*Symposium: Corneal Transplantation**

I. SELECTION OF CASES

R. TOWNLEY PATON,† M.D.
New York

No general rule may be applied for the selection of cases favorable for corneal transplantation. Each case must be dealt with individually, and a general appraisal made. In studying the patient's eye condition, the following factors must be taken into consideration.

Environmental Factors. What are the indications and need for the operation? A patient with reduced vision as a result of a scarred cornea, but who is well-adjusted to his environment and self-supporting, might better be left alone, even though the corrected visual acuity is below 20/200 in either one or both eyes. This is especially true if the eye falls into that group of cases which is designated as doubtful for the improvement of vision. This group of cases will be considered in more detail later. The ophthalmologist should be especially guarded in giving advice to one-eyed patients.

The physical condition and age of the patient are important factors, as in other types of intraocular surgery. Examination should include a medical survey such as is usually done preliminary to cataract operations. Some knowledge of the patient's psychologic reactions should also be known. Highly nervous and poorly emotionally adjusted persons make especially poor candidates for this type of ocular surgery.

Age Group. Another important factor to remember is that corneal grafting cases belong to a much lower age group than do cataract patients. A failure following a cataract operation does not lead to quite as serious consequences from an emotional and economic point of view. Most cataract patients have reached the retiring age and do not look forward to a very active life. Successful operations have been performed however on babies as well as people in their seventies and eighties. Transplantation in the very young is to be avoided because of the difficulty in the handling of the patients. Early postoperative dressings have to be done under general anesthetic, and if a small stitch abcess or some other type of infection develops, the surgeon is greatly handicapped. A sudden or violent movement during the early postoperative stage might cause a collapse of the anterior chamber and resulting anterior synechias as well as a dislocation of the graft.

Iridectomy. No case of scarred cornea should be operated on if an iridectomy would bring about an improvement in vision. Just how much improvement in vision should be obtained by an iridectomy must be left up to the patient to decide. The greater risk of performing a corneal transplanting operation should be explained to him. Before making

* Presented at the 52nd annual session of the American Academy of Ophthalmology and Otolaryngology, October 12 to 17, 1947, Chicago. For the discussion of this symposium see: Tr. Am. Acad. Ophth., March-April, 1948, pp. 347-353.

† From the Manhattan Eye, Ear and Throat Hospital.

this decision it is well to see how much improvement in vision may be obtained by dilating the pupil. If there is material improvement in vision, there can be no question that an optical iridectomy should be performed. In doubtful cases there is no great disadvantage in first doing an iridectomy. If there is no improvement in sight, a transplant may subsequently be performed. If the

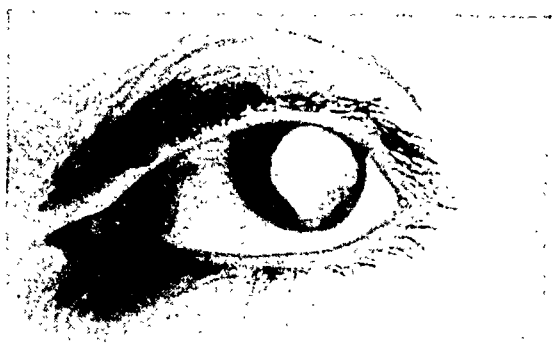

Fig. 1 (Paton). Dense leukoma with some clear surrounding cornea favorable for operation if no corneal blood vessels are present.

cornea is so densely scarred that the pupil cannot be seen, transillumination should always be done, and an accurate idea obtained as to the size and shape of the pupil.

CLASSIFICATION OF CASES FOR OPERATION

1. Favorable for improvement of vision
2. Partially favorable for improvement of vision
3. Unfavorable for improvement of vision
4. For cosmetic improvement
5. For treatment of descemetocele
6. Where preliminary surgery or treatment is necessary before final opinion may be given

1. *Favorable for improvement of vision.* The most favorable cases are those in which there is a nebulous type of opacity, quite central, and in an otherwise normal eye. There must be no active corneal disease present, nor active infection of the conjunctiva, sclera, or uveal tract. There must be no increased intraocular pressure, and no vascularization of the cornea. Blood staining of the cornea and conical cornea are usually favorable cases.

A very definite policy in the selection of conical cornea cases should be followed. At our clinic no case is operated on if the visual improvement with correction is better than 20/200 in either one or both eyes. This also includes those cases where vision can only be improved by means of a contact glass.

An exception is made in those cases that do not tolerate the wearing of contact lenses, or where there has been a rapid deterioration of vision due to the development of central corneal opacities. It would seem more advisable to operate on these cases early and do as large a graft as seems feasible. It is interesting to note that the contact glass, if necessary for the improvement of vision, although not well tolerated before the operation, may usually be worn with comfort after operation.

2. *Partially favorable for improvement of vision.* Partially favorable cases include those in which there is some corneal vascularization present such as in old cases of interstitial keratitis, and where the opacity, although

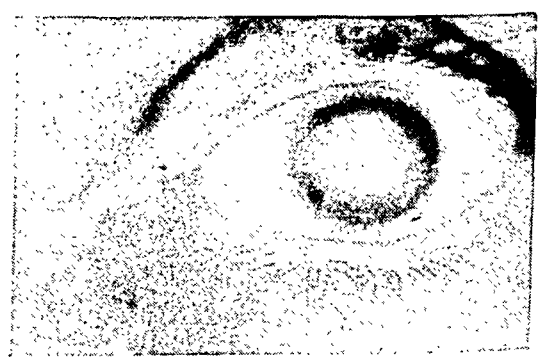

Fig. 2 (Paton). Large central corneal opacity with many fine peripheral blood vessels seen with the slitlamp—also surrounding cornea faintly opaque—not favorable for operation.

central, is not too dense and with only a small amount of clear cornea surrounding it. Cases of adherent leukoma do not do well as a rule, unless the adhesions are first destroyed by a preliminary operation or irradiation. An extremely shallow anterior

chamber adds little to the technical difficulties of the operation, although there may be greater danger of anterior synechias forming after the operation.

The diagnosis of glaucoma in the presence of keratectasia or keratoconus is most difficult to make. Its presence should always be suspected. A Bailliart type of tonometer may be helpful, as with this instrument the degree of scleral rather than corneal indentation is measured. If there is any doubt concerning the diagnosis of glaucoma, an attempt should first be made to lower the intraocular pressure by one of the filtering types of operations.

Most cases of corneal dystrophy are not favorable for corneal transplantation. This is especially true of the Fuchs's endothelial and epithelial types of dystrophy. From present knowledge it would appear advisable to operate early in the course of the disease when the opacification of the cornea is not too dense and does not include all the layers of the cornea.

Salzmann's[5] corneal dystrophy usually has some blood vessels present, but if these vessels can first be destroyed by irradiation, the transplant should be attempted on one eye, if the other eye has useful vision.

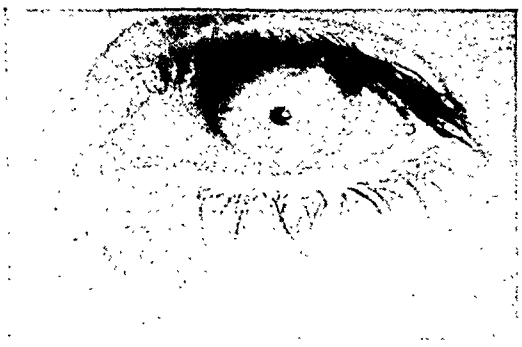

Fig. 3 (Paton). Descemetocele about to rupture—corneal transplantation indicated although no improvement in vision can be expected.

Groenouw's[3] dystrophy appears to give a more favorable result. Here again it is a question of degree and density of the opacification of the cornea. Some cases of fatty or lipoid degeneration of the cornea may be favorable for operation. Calcareous degeneration, if it involves the entire cornea and the full thickness of the cornea, should not be operated on. However, if the degeneration is band-shaped and not too dense, with some clear corneal tissue surrounding the scarred area, corneal transplantation should be performed.

Fig. 4 (Paton). Conical cornea ideal for corneal transplantation.

3. Unfavorable for improvement of vision. These are cases with marked nystagmus, as these eyes are amblyopic and, although a clear graft may be obtained, the visual results are disappointing. Densely scarred corneas from powder burns do poorly following transplantation. The same applies to lime burns of the cornea, but only if all the layers of the cornea are involved.

Any eye which is hypersensitive to light trauma—for example, such as might occur in measuring the intraocular pressure—should not be operated on until the cause of the hypersensitivity is discovered. Little experience has been had in operating on old trachomatous eyes, but the general principles laid down concerning degree of vascularization and opacification would hold in the selection of these cases for operation.

4. Cosmetic improvement. Many cases where tattooing was formerly resorted to in order to hide a disfiguring scar might be improved by corneal transplantation. In some few cases, an improvement of vision may be obtained, although this is not the general rule due to many complicating fac-

Fig. 5 (Paton). Groenouw's corneal dystrophy favorable for operation.

tors. In general, tattooing and corneal transplantation do badly in the presence of a highly vascularized cornea.

5. Treatment of descemetocele. There is perhaps no more favorable treatment of descemetocele than corneal transplantation. Cauterization and repeated paracentesis are usually palliative measures. Conjunctival flaps only add to the disfigurement of the patient's eye, and often the flap becomes incarcerated in the wound. Transplantation should not however be attempted if there is a markedly increased tension or in the presence of large corneal blood vessels. The degree of vascularization should be one of the most important and determining factors.

Where there is extensive vascularization of the cornea, preliminary radiation (Iliff[4]) should be performed, and unless all the larger vessels are completely destroyed, keratoplasty is bound to meet with failure. It is true, however, that in a few cases where

Fig. 6 (Paton). Unfavorable for operation because of vascularity.

smaller blood vessels have been present before operation, after the transplant operation has been done, the vessels will grow to the edge of the graft and tend to extend along the scarred area without actually penetrating into the graft itself. Apparently the scarred tissue formed in the cornea following a transplant operation will act as a barrier against their invasion, but it is not wise for the surgeon to depend on this, as there is no way of predicting whether the vessels will penetrate the graft or not.

6. Preliminary surgery or treatment necessary. It is not always necessary to do preliminary surgery for anterior synechias, for

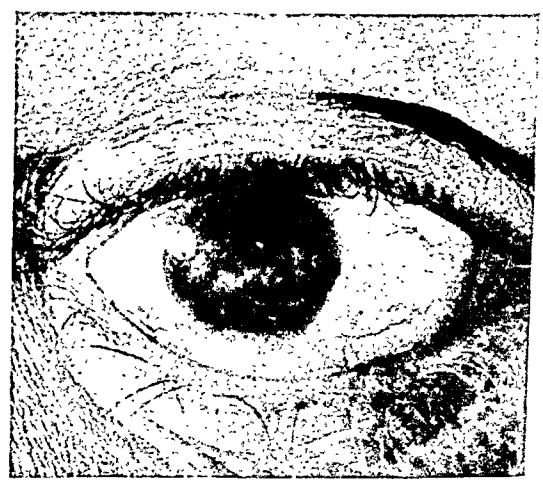

Fig. 7 (Paton). Diffuse nebulous opacification involving the anterior third of the cornea —ideal for corneal transplantation. Preoperative vision, 20/200; postoperative, 20/15 with correction.

if they are small and of delicate structure, these can be attended to at the time of operation.

It is poor surgical judgment to operate on any case in which there is an active uveitis present, but it is an interesting fact that several cases have been operated on in which, immediately after the operation, a recurrence of a previously active uveitis was noticed, with large keratic precipitates noted on the posterior surface of the graft. All these cases made an uneventful recovery and the keratic precipitates have since disappeared.

One such case has been followed for a period of three years with no recurrence of the uveitis, and the transplant has remained clear. The same may be true in dealing with scarred corneas in conjunction with episcleritis.

I have had no experience with therapeutic keratoplasty but many references have appeared in the literature advocating its efficacy. Feldman and Shartz[1] and Filatov[2] advocate a partial penetrating keratoplasty for such conditions as serpent ulcer and tubercular interstitial keratitis. It does not appear to me, however, that this form of treatment is advisable excepting as a last resort measure.

Little has appeared in English literature concerning partial nonpenetrating keratoplasty, but from foreign reports it would appear that the results of this method are nearly as good as results from a penetrating type of keratoplasty and may be less hazardous. It may be that this method may eliminate the need for keratectomy in many instances. It is not the purpose of this presentation, however, to discuss this subject.

927 Park Avenue (28).

II. TECHNIQUE

JOHN M. MCLEAN,* M.D.
New York

In my portion of this symposium, I plan to cover the actual surgical techniques of corneal grafting, both in a brief survey of their development and in a more comprehensive discussion of those in use at present, and the methods of obtaining and preserving donor material. Time will not allow a complete recital of the many steps which have led up to present techniques but I shall try to touch on the more important ones.

HISTORICAL SURVEY

Although attempts at corneal grafting had been made before, the first important step was that of von Hippel in 1887.[16] He cut a round graft from the center of the scarred cornea and replaced it by a similar round plug of tissue from a donor eye with clear cornea. His grafts were not beveled. They were not held in place by any sutures. They were not sufficiently satisfactory to stimulate many others to try his technique. However, they did point the way for further development.

The next significant step was made by Zirm, in 1906,[18] when he introduced the idea of holding the graft in the recipient cornea by overlying sutures. These sutures crisscrossed the graft from limbus to limbus and added an important feature to the developing operation.

Elschnig, in 1911,[4] took further steps following the technique of von Hippel. His results would not be considered up to modern standards but he did add encouragement to subsequent workers in this field.[5,6,13]

In 1928,[7] Filatov added a number of innovations. His use of preserved donor material will be considered later. He used a hand trephine and several different types of prophylactic spatulas.[8] These spatulas were introduced across the anterior chamber to protect the lens and iris from inadvertent damage by the trephine.

Further refinements in protective spatulas have been suggested by Paton but these devices are no longer widely used. The reasons for abandoning them are several and include further complication of the technique, additional incisions and softening of the eye, increased opportunity for anterior synechias, and even of iris prolapse.

Filatov also advocated the use of inverted conjunctival flaps or, in the absence of adequate conjunctiva, of egg membrane to hold the graft in place instead of sutures. Further investigations in substitutes for sutures are now in progress in this country. As yet they have not had adequate trial and nothing has been published on these methods. Conjunctival flaps and egg membrane have not proved sufficiently strong to compete with directly overlying sutures.

Thomas, in 1930,[14] published his methods which introduced certain new concepts. He used a considerable bevel of both graft and recipient site. This bevel was attained by oblique trephining and the use of scissors to complete the incisions. Such an incision, *of course, did not produce a perfect truncated* cone but was close enough to be practical and has been used until relatively recently by various surgeons.

One of the principal objectives was to prevent the graft from falling into the anterior chamber, but this has proved to be unnecessary when the graft is cut to the exact size of the incision in the host cornea. Thomas,[15]

*From the Department of Surgery (Ophthalmology), The New York Hospital, Cornell University Medical School.

however, did not do this but deliberately cut the graft smaller than the host incision to allow for early postoperative swelling of the graft. He used multiple corneal sutures (usually two), directly over the graft, but not into it. These sutures, placed directly into the cornea just beyond the edges of the graft, held much tighter closure than the previously used limbus-to-limbus overlying sutures or conjunctival flaps.

Castroviejo, in 1932,[1] described his new technique. He used a square graft accurately outlined by parallel knives and cut with keratome and scissors. At first he advocated a bevel of 45 degrees at all of the edges. This was to increase the area of corneal healing as well as to keep the graft out of the anterior chamber. As time went on,[2] he decreased the angle of bevel down to his present technique of straight edges, as the use of a bevel became obviously less and less necessary.

He also advocated a single continuous overlying suture as near the graft edges as possible. The argument for a single continuous suture was that it would adjust itself better for even distribution of pressure on the graft. At first this suture was untied; later, tied.

Castroviejo[3] has also experimented a great deal with round grafts. In the days when he believed in the importance of a bevel he devised a number of ingenious devices for cutting a perfectly beveled round graft. They were never completely perfected because the idea of beveling the sides of the graft was discarded.

Various techniques

The various techniques of keratoplasty which must be considered are total keratoplasty, rotating autokeratoplasty, superficial lamellar keratoplasty, and partial penetrating keratoplasty. For general use the last is by far the most practical and has the widest application.

Total keratoplasty[10,17] has had sufficient trial in animal experiments and human cases to be discarded. It is not successful in practical application and not feasible on theoretical grounds.

Rotating autokeratoplasty,[9,11] while theoretically sound, does not work well in practice. It consists of the rotation of a large circular disk, or end-for-end transfer of a larger rectangle of cornea in the involved eye to replace cloudy central cornea by clear peripheral cornea of the same eye.

Superficial lamellar keratoplasty[12] is theoretically feasible but very little used in this country. Since it is a form of nonpenetrating keratoplasty, there must be an area of wound union all the way across the base of the graft with some attendant scarring. For most surface scars, superficial keratectomy is simpler and just as effective. However, in certain cases of deeper scarring where any form of penetrating keratoplasty seems to introduce excess risk, it must be considered.

An example of this would be a case of aphakia with bulging vitreous. Here the risk of vitreous loss and vitreous incarceration at the edges of the graft might outweigh the better visual prospects of an uneventful penetrating graft and militate in favor of the safer, if visually poorer, nonpenetrating graft.

The partial penetrating corneal graft is the most successful method in ordinary cases.

Although there are individual variations in technique of these grafts, the principles are well established. The graft must be in contact, in as great an area as possible, with good corneal stroma. This does not mean that it must necessarily be in contact with clear surface cornea, but it must form union with good corneal stroma whether overlaid or not by scars on the surface. This requirement affects somewhat the size and location of the graft. If it is not fufilled the graft need not be lost but satisfactory clarity is not to be expected.

Recent trends in technique

Size of grafts. The gradual swing in re-

cent years from small grafts to larger and larger grafts has been attended by greater visual success. There is always some scarring at the edges of the graft, and if this is of significant width it may tend to encroach on the central visual area of a small graft. The same width scar will not approach the center of a larger graft. There are also outside limitations to the size of the graft. It must not be large enough to interfere with the angle of the anterior chamber nor to allow iris incarceration or prolapse at the edges.

It is now known that beveling of the edges of the graft or recipient cornea is not necessary although in former years much attention has been given to this feature.

Sutures. Some means of holding the graft in place is important and the present methods are all variations of the overlying suture. For more secure closure it is obvious that the sutures should be placed in recipient cornea as close to the graft edges as possible.

It probably makes little difference whether a single continuous suture is used or multiple sutures. As long as adequate and even, but not excessive, pressure is attained, this requirement is fufilled. Although I personally prefer the continuous, single, tied suture because of its ease of even adjustment, I can find no fault with multiple sutures if they are properly adjusted.

Direct suturing of graft to recipient cornea introduces unnecessary additional trauma to the graft and is to be avoided in the ordinary case. Certain special situations where it must be used will be discussed in the section dealing with complications. Omission of sutures and use of other devices for securing the graft are generally unsatisfactory.

Shape of graft. The shape of the graft is not of major importance. The two popular shapes are round and square. Both are easily obtained. The arguments for a round graft on a cosmetic basis are not particularly relevant. In the first place, the primary objective is restoration of vision. Slight improvement in appearance is a very minor consideration. In the second place, the sharp corners of a square graft tend to appear rounded in due time in many instances. The important factors are not initial shape but accurate fit and smoothness of the edges.

Probably the high-speed mechanical trephine is the best means of cutting a true-edged graft. Of the various methods of cutting grafts by hand, the square technique by double-bladed knife, keratome, and straight-bladed scissors is probably easiest. The method of hand trephine and curved scissors seems somewhat harder and less likely to give a perfect fit but can be mastered. The principal objection to the high-speed trephine is its greater risk of injuring the lens. In the final analysis, the shape and method to be used are those found safest and most satisfactory in the hands of the individual surgeon.

Anesthesia. In addition to these major principles there are other factors in surgical technique which deserve mention. Anesthesia is local by choice and should consist of adequate topical anesthesia plus retrobulbar block. Complete akinesia is also important. The local anesthesia may be further supplemented, if desired, by subconjunctival injection. If for some reason general anesthesia is required, the method of choice is intravenous pentothal and the inhalation anesthetics are to be avoided because of their after-effects. It is well to supplement pentothal by deep orbital block.

Asepsis. Complete aseptic technique is, of course, of major importance but needs no detailed discussion here. Since the graft is obtained from another patient whether living or postmortem, it seems wise to use prophylactic penicillin in all cases.

Dilatation of pupil. Although some surgeons who use trephine techniques like to use miotics before operation and mydriatics at the end, a widely dilated pupil to avoid synechias and incarcerations is important.

Therefore, it seems better to dilate the pupil widely before operation with such drugs as atropine and strong neosynephrin, to reinforce the mydriasis with subconjunctival injection such as cocaine and adrenalin, and even to place a drop of adrenalin, or adrenalin and atropine, directly into the anterior chamber during the operation.

Postoperative care. At the end of the operation binocular dressings with moderate pressure should be applied and the patient treated much as a detached retina patient is managed. However, moderate elevation of the head of the bed is in order. The surgeon should hold his curiosity in check and avoid early and frequent dressing which may serve more to interfere with healing than to promote it. After the sutures are removed, further pressure dressings are advisable.

The operation is easy enough so that it can be mastered by any competent intraocular surgeon, but it is different enough from other ocular surgery that it should not be entrusted to or attempted by a surgeon who has not had considerable experience in developing his technique through many animal grafts.

Donor material

The final portion of this part of the symposium deals with donor material. Years of experiment and experience have determined certain facts which can be stated rather arbitrarily. The material must be corneal tissue. Attempts to use buttons of glass, plastics, and other tissues have all been unsuccessful.

Donor cornea. The donor cornea may be from a fresh eye which has just been enucleated or from one which has been satisfactorily preserved. Most of the latter are postmortem eyes. In either event the cornea must be in good condition, free from local disease; uncontaminated, and from a patient who is free from communicable disease, including syphilis. Whether late latent syphilis or adequately treated syphilis can be transmitted by a corneal graft is a moot question. However, this question is one which surgeons do not care to risk answering by human experiment.

It has been found out by experience that race, age, sex, and blood grouping are not important factors and do not influence the result of the operation. But the donor cornea must be human. Other species cannot be substituted. If they are, the graft may take but will not stay clear.

Preservation of materials. Prior to 1944, there had been a few isolated attempts to preserve donor eyes for short periods of time. Filatov was organizing an "eye bank" in Russia but very little had been done in this country. In that year Dr. Paton and I set up an experimental "eye bank" at the New York Hospital.

Postmortem eyes were obtained from the general wards of the hospital and a few nearby coöperating hospitals. The eyes were enucleated under aseptic operating room conditions, placed in suitable physiologic solutions, and kept in a portion of the blood-bank refrigerator until used.

This pilot experiment proved the practicality of such an "eye bank" and the advisability of starting such a bank which would be available to surgeons in all hospitals but independent of any one hospital. In early 1945, The Eye Bank for Sight Restoration was incorporated. Everyone in this audience is familiar with its history. It has proved to be most useful in providing material for corneal grafting.

For the eye departments of large general hospitals, it is helpful in providing donor material at the time it is needed, if there is none locally available at the time.

For the smaller hospitals and the isolated specialty hospitals it has proved an indispensable boon in supplying material that might otherwise never be obtained. As a clearing house, it serves to prevent waste of donor material not needed at the time at its hospital of origin.

Postmortem eyes should be obtained as soon as possible after death, preferably within 4 to 6 hours. They are then stored at the temperature used for preserving blood (about 4° C.). At present the best method of storage is in a tightly sealed container in a saturated atmosphere of water vapor. The allowable time of storage has not yet been well worked out. It is best to use the donor eyes as soon as possible.

The best index of suitability is not the elapsed time but the condition of the cornea on close inspection. At first it was arbitrarily thought that the fresher the cornea, the better donor material it would be. Subsequently, Filatov, the advocate of preserved tissue therapy, felt that storage improved the condition of the cornea. In practice, it seems to make little difference whether the cornea be stored or not, as long as its condition is good at the time of operation.

Conclusion

In conclusion, then, the operation of corneal transplantation has become an accepted, useful procedure, the general principles of which are well established. So long as they are adhered to, many minor variations in technique can be introduced to suit the individual surgeon. The institution of "eye banks" materially aids in the securing and distribution of donor material.

III. COMPLICATIONS

RAMON CASTROVIEJO,* M.D.
New York

Only the complications taking place in cases which have been classified as favorable for keratoplasty will be discussed in this presentation.

This study is based on the observation of about 1,000 keratoplasties including the operations performed by me and those done under my supervision in the United States and elsewhere during the past 17 years. I have purposely included in this study all the complications that I have observed in my cases and those of others in order to be able to mention in this presentation the complications encountered by surgeons with both extensive and limited experience in corneal transplantation.

Some of the complications occur during the operation, others during the first few days or weeks of the postoperative recovery, still others several weeks or months after the operation. Only the treatments that have been found to be most effective in the handling of these complications will be described.

The two types of keratoplasty, square and circular, that I have advocated and on which this study is based are illustrated in Figure 1, A and B. Figure 2 shows the double-bladed knife (A), keratome (B), and special scissors (C) used in the square-graft technique, the trephine (D and E), and special scissors (F) used in the circular-graft procedure.

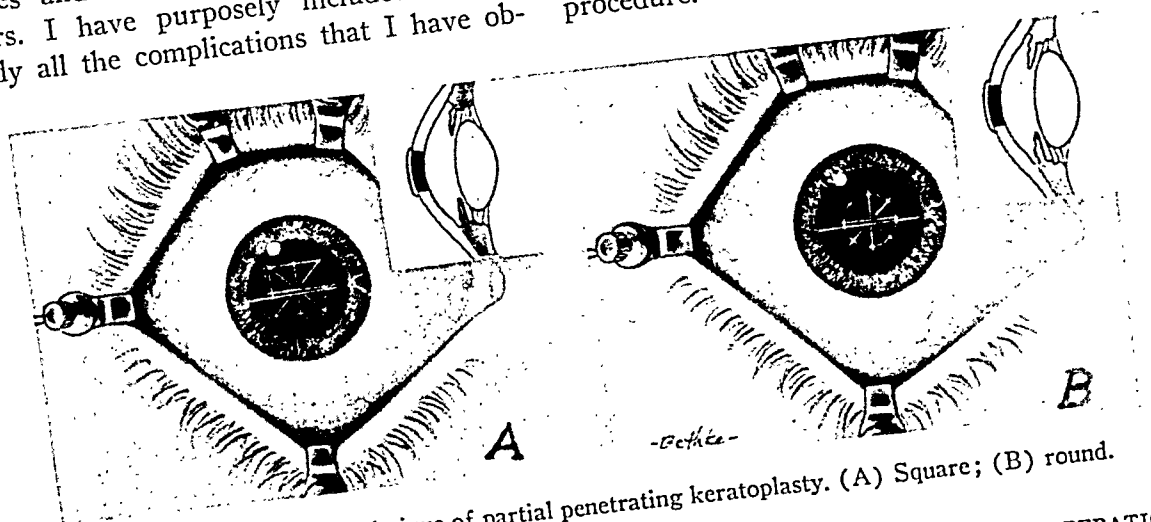

Fig. 1 (Castroviejo). Technique of partial penetrating keratoplasty. (A) Square; (B) round.

COMPLICATIONS DURING THE OPERATION

While preparing the operative field, irritating solutions such as iodine or alcohol may enter the recipient's eye and destroy part or all the corneal epithelium. This complication will not necessitate the postponement of the operation. The surgical procedure will of course be more difficult since the outlining of the incisions with fluorescein or other solutions will not be as effective.

Even though the operation may be somewhat more complicated than with an intact epithelium, the final outcome, as far as visual

* From the Institute of Ophthalmology, Columbia-Presbyterian Medical Center.

purposes are concerned, will not be affected and the epithelium will regenerate completely. Without epithelium, however, there is more opportunity for infection and possible subsequent opacification of the graft.

The same accident mentioned in the case keratectomies. This complication makes it difficult to continue the operation.

Two choices are suggested, either to postpone the operation for about a week to give time for the anterior chamber to reform and for the cornea to close the opening firmly, or

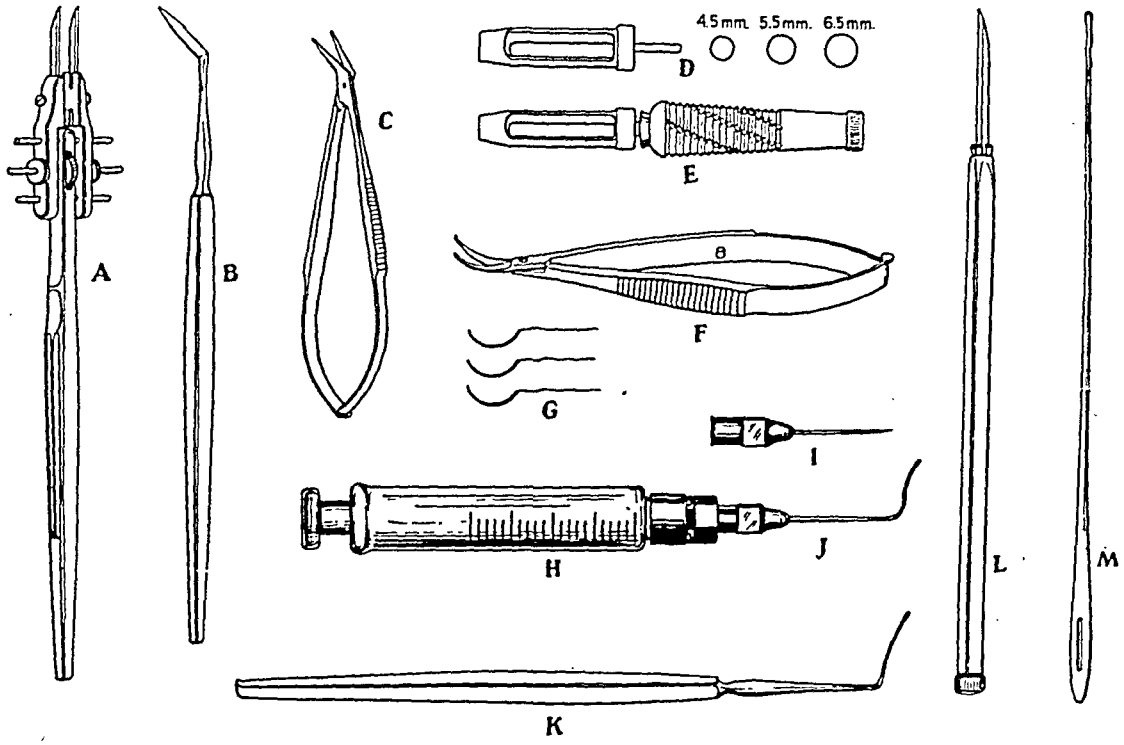

Fig. 2 (Castroviejo). Instruments required for described methods of square and circular partial penetrating keratoplasty and for the treatment of anterior synechia. (A) Double-bladed knife; (B) keratome; (C) special scissors for the square graft; (D) and (E) trephines; (F) special scissors for the circular graft; (G) atraumatic needles with 6-0 silk; (I) fine hypodermic needle for air injection in the anterior chamber; (J) Randolph cannula with syringe (H); (K) Cyclodialysis spatula, 15-mm. long; (L) utility knife; (M) probe.

of the recipient's eye may take place in the donor's.The donor's eye should, of course, be used undamaged if possible. The graft may be transplanted without epithelium and remain transparent with complete regeneration of the epithelial covering.

If the incisions have been placed off center in the cornea, new incisions can be made in a better position without interfering with the subsequent steps in the operation.

While outlining the incisions, the cornea may be perforated. This is particularly prone to happen in very thin corneas, such as in cases with advanced keratoconus, or in those eyes which have undergone preliminary

to proceed with the operation.

Although with more difficulty, the surgeon well trained in keratoplasty will be able to place the sutures even after the cornea has been perforated, particularly if the suture material is good. Of course, in this eventuality, the remaining uncut portion of the incision has to be completed, in the square as well as the circular-graft technique, with the aid of scissors.

While inserting the sutures, in thin corneas particularly, the needle may enter the anterior chamber. In this complication the aqueous humor will drain slowly rendering the eye hypotonic. This complication may

be taken care of by withdrawing the needle and passing it through more superficial layers of the cornea. Otherwise, a fistula may form during the postoperative recovery with drainage of the aqueous humor and flattening of the anterior chamber and likelihood of subsequent development of anterior synechias and intraocular infection. If there is any doubt about the location of the suture on the second attempt, it would be preferable to postpone the surgical procedure rather than risk the success of the operation.

While inserting the sutures, particularly if a continuous one is employed with an atraumatic needle, the needle may break. This can be remedied either by threading the silk on a regular needle and proceeding in this way until the suture has been completed, or by recommencing the suture, inserting a new one through the channels already made.

While manipulating the instruments after the suture has been inserted the thread may be cut. This complication can be handled by tying a knot where the silk was cut. At the completion of the operation, the knot should be drawn away from the graft to prevent its opacification at the site of pressure from the knot on the graft. This cloudiness no matter how slight, if it occurs in the center of the graft, may reduce vision considerably.

The lens may be injured by the keratome in the square-graft technique or, more likely, by the trephine or by the scissors while completing the incision. In any event, this is one of the most serious complications. The most satisfactory way of dealing with this situation is to complete the dissection of the recipient's cornea and the graft, remove as much as possible of the injured lens including the capsule, and place the transplant in position tying the suture which was previously inserted.

In this complication, the vitreous has a tendency to prolapse during the operation and to dislocate the graft with subsequent opacification of the graft, secondary glaucoma, or panophthalmitis. Therefore, it is advisable in these cases, in order to maintain the graft firmly in position, to suture the four corners in position in the square graft or to place four sutures at opposite ends of perpendicular diameters in the circular graft. The patients in whom this accident takes place rarely recover with useful vision.

When, after perforation of the anterior chamber, the pupil is found to be contracted, smaller than the opening made in the cornea of the host, a direct instillation of cocaine (4 percent) and adrenalin (1:1,000, or even 1:100), into the corneal opening, may dilate the pupil wider than the corneal window. If, in spite of the instillations, the iris shows within the opening, it is advisable to excise the involved portion of iris rather than to risk the development of an anterior synechia.

The performance of an iridectomy in these cases will, of course, be questioned by those who perform keratoplasties with contracted pupils. Statistics will show in the future which method gives the greater number of anterior synechias, the one of the contracted or the one of the dilated pupil.

In my experimental work in animals, the method of contracted pupil was discarded because it had a much greater tendency to develop anterior synechias. My experience in human beings has verified the findings of the experimental work.

Inexperience, particularly with the square-graft technique may lead to irregularities in the shape of the corneal window or the graft. This complication can be avoided by mastering the operation through training with animals' eyes. If it should occur, it can only be corrected if the cornea of the host is dissected before the graft. In this case the graft can be shaped to conform with the asymmetry of the corneal opening in order to obtain a better coaptation of the borders. If the graft or its bed is made with excessive beveling or an irregular inner edge, the condition can be adjusted by careful dissection with scissors.

In cases of very large grafts, particularly in advanced keratoconus where the cornea is

thin and collapses as soon as the anterior chamber is opened, it is sometimes very difficult to hold the graft in position. In these cases, direct suturing of the border of the cornea of the host with that of the donor is to be recommended. At least four sutures placed in the corners of the square graft or at the ends of two perpendicular diameters in the circular graft are advisable.

Complications during the postoperative recovery

The dislocation of the transplant within the eye is a complication which I have not encountered. I have observed the complete displacement of the graft outside the recipient's corneal opening. This complication is very serious and should be treated by reimplanting the same graft, if this is available, by suturing its borders with those of the host's cornea. If the graft has been lost, a new one must be prepared and sutured in place.

If neither the original transplant nor a second graft can be obtained, the use of a conjunctival flap is the only method of closing the opening and protecting the eye. I have not observed any case in which useful vision has been preserved after this very serious complication. This condition is generally observed at the first dressing. It is more likely to occur in the uncoöperative, high-strung type of patient.

If the transplant is only partly detached, the postoperative course may be stormy with the formation of a fistula and anterior synechias. Conservative treatment may sometimes result in complete cicatrization of the dehiscence with preservation of fairly good or complete transparency of the graft. If, however, this partial prolapse should be extensive, it is advisable to coapt the borders of the graft and the border of the host by direct suturing.

Occasionally, in corneas which are very thin, such as keratoconus, at the time when the corneal sutures are removed, there may be a collapse of the anterior chamber with loss of aqueous humor. Very seldom, however, is this opening extensive and almost always the transplant cicatrizes well, without complications such as development of anterior synechias.

If hernia of the iris develops, it is advisable to wait until the third postoperative week and then, when the rest of the transplant has become solidly attached to the cornea of the host, the hernia should be excised and the edges of the graft and cornea of the host coapted by direct suturing.

All cases in which the transplant has been partly or totally displaced are likely to develop endophthalmitis. Therefore, in addition to the treatment of the eye, prophylactic treatment by intramuscular injections of penicillin should be carried out; also foreign-protein therapy, preferably intravenous injections of typhoid, should be administered as soon as intraocular inflammation is apparent.

The development of anterior synechias is one of the most frequent complications in keratoplasty, particularly in cases with large grafts where the cornea is thin, such as advanced keratoconus or in eyes where the cornea has been thinned by ulceration or preliminary keratectomy.

If the synechia is smaller than 2 mm., occasionally the use of atropine or eserine loosens it. If the synechia is more extensive it will necessitate surgery in order to prevent opacity, vascularization of the graft, and secondary glaucoma.

The surgical treatment of the synechia must not be carried out before the 14th day postoperatively because until then the union of the graft with the cornea of the host is not very firm, and premature surgery might lead to dislocation of the graft. The operation, however, should not be delayed beyond three weeks, otherwise the graft may already have become opaque on account of the synechia. Therefore, the best time to carry out this surgery is in the third postoperative

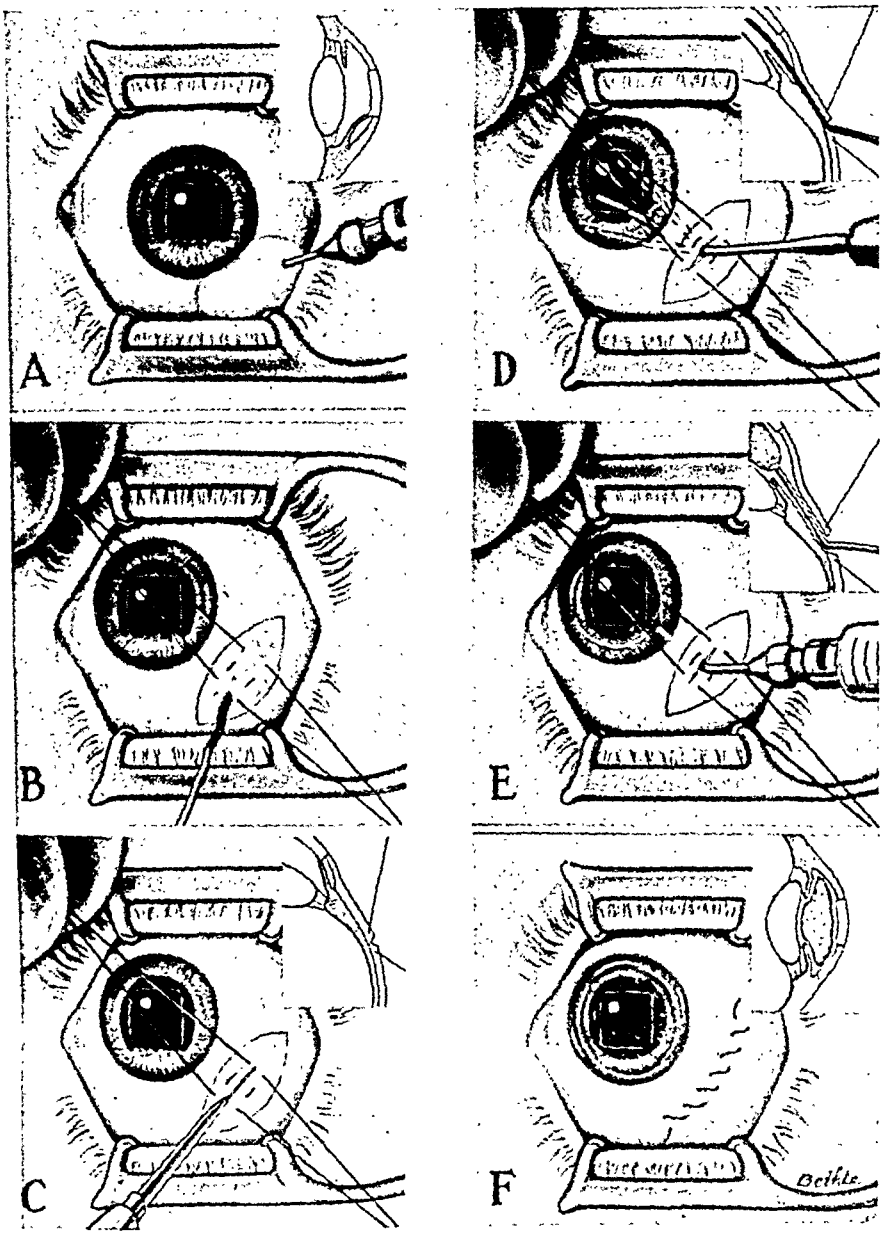

Fig. 3 (Castroviejo). Successive steps in the technique for the treatment of moderate anterior synechias.

week and preferably under general anesthesia.

Surgical techniques for the treatment of anterior synechias

If the synechia extends from one fifth to one half of the circumference of the graft, the operation of choice is as follows.

Depending upon the location of the synechia, the incision in the sclera is made in the quadrant nearest the synechia; the lower temporal for synechias in the lower half, and the upper temporal for synechias in the upper half of the transplant.

A routine preparation of the eye, about one hour before the operation, is made with instillations of atropine (1 percent) and neosynephrin (10 percent) in order to obtain as wide a dilatation of the pupil as possible. At the time of the operation, after routine preparation of the eye, argyrol (25 percent), a 4-percent solution of cocaine, and a solution of adrenalin (1:1,000) are instilled into the eye. A few drops of cocaine and adrenalin

(1:1,000) are injected under the bulbar conjunctiva (fig. 3A) with the purpose of obtaining ischemia, wider dilatation of the pupil, and to counteract a tendency to contraction after the anterior chamber has been opened.

An incision is made through the conjunctiva and Tenon's capsule about 7 mm. from the limbus and parallel to it (fig. 3B). Two 2-0 silk sutures are inserted in the sclera, 4 and 6 mm. from the limbus and parallel to it. These sutures are used for fixation; one of them is held by the assistant and the other by the surgeon. The area of the sclera between the two sutures is treated by superficial electrocoagulation or by a hot probe to obtain a bloodless operative field (fig. 3B).

With the knife an incision is made in the sclera similar to that performed for cyclodialysis (fig. 3C). When the sclera has been perforated and the choroid is reached, a

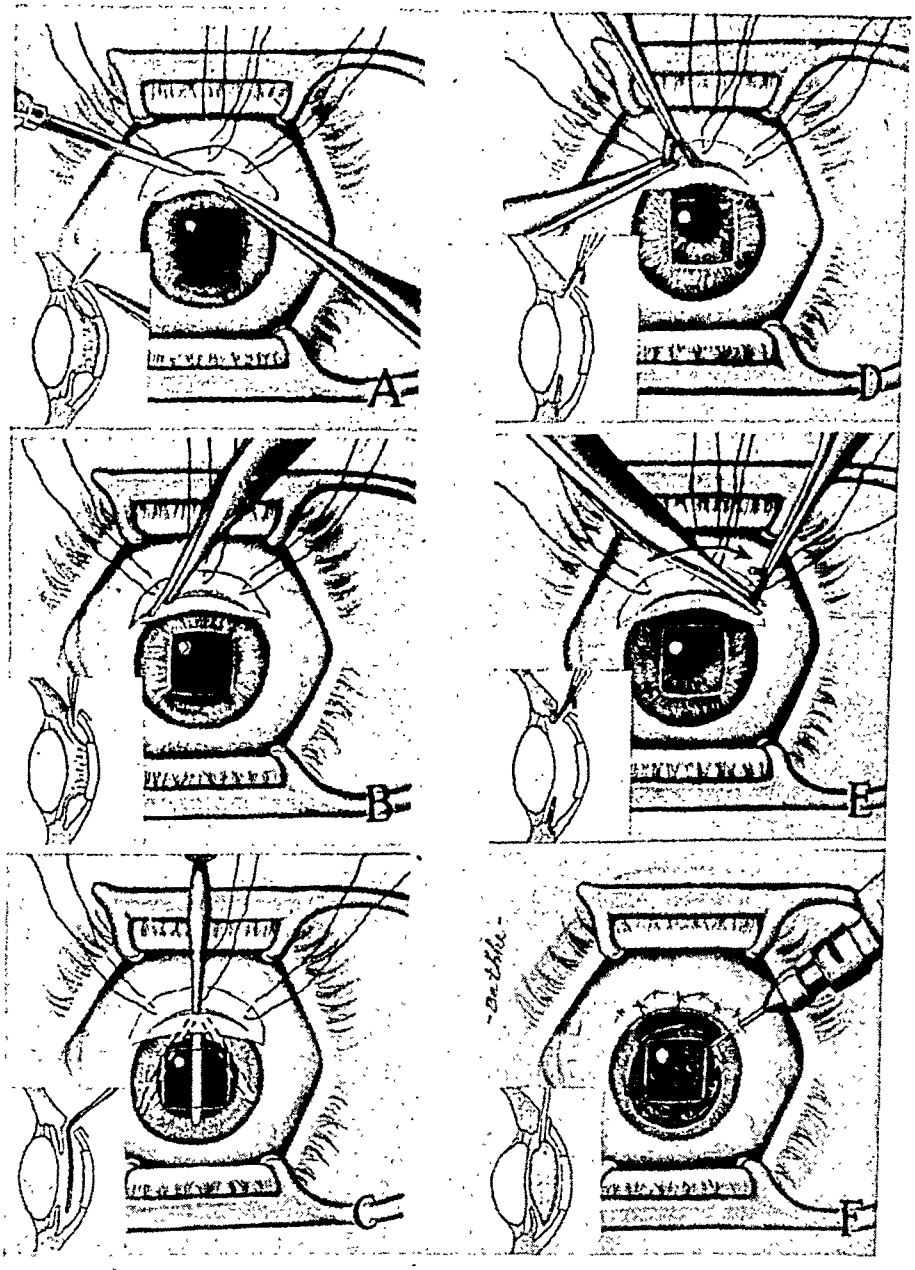

Fig. 4 (Castroviejo). Method of treating extensive anterior synechias.

long spatula similar to that used for cyclodialysis, but 15 mm. in length (fig. 2K), is introduced through the scleral opening and then between the sclera and choroid, into the anterior chamber. The adherent iris is separated from the cornea with the aid of the spatula (fig. 3D). The spatula is then withdrawn and the tip of a Randolph perforated cannula (fig. 2J) with the shape of a cyclodialysis spatula attached to a syringe (fig. 2H and 2J) is introduced in the same manner as the spatula into the anterior chamber and air is injected to push the iris away from the cornea (fig. 3E). The cannula is then withdrawn and the conjunctival incision closed with a continuous 6-0 silk suture. This cyclodialysis incision several mm. from the limbus is preferable to incisions in the limbus because with the latter it is not always possible to keep the air within the anterior chamber long enough to prevent the recurrence of the synechia.

When the synechia is very extensive, the operation which I found satisfactory is as follows.

The operation should be carried out preferably under general anesthesia. With the aid of scissors and conjunctival forceps, a conjunctival and episcleral flap of 2 to 3 mm. between the 10- and 2-o'clock positions is made around the limbus (fig. 4A). The conjunctival flap is reflected down over the cornea and three 6-0 silk sutures mounted in atraumatic needles are inserted, one at the 12-o'clock position and the other two equidistant between the central one and the ends of the conjunctival incision. The sutures are passed first through the conjunctiva and then through the sclera entering the sclera about 2 mm. from the limbus and taking a bite of about 1 mm. (fig. 4A). The sutures are now drawn out of the way in order to make the incision with a minimum of interference.

With the knife an ab-externo incision is made at the limbus around the 12-o'clock position (fig. 4A). When the anterior chamber is entered the incision is enlarged temporally and nasally with the aid of scissors (fig. 4B). With the cyclodialysis spatula the iris is then separated from the cornea (fig. 4C). A large iridectomy from the 10- to 2-o'clock positions is then performed (fig. 4D and 4E). The sutures are then passed through the corneoconjunctival junction, including a small bite of corneal tissue, and tied. Additional conjunctival sutures are inserted and air is injected into the anterior chamber (fig. 4F) in an effort to push the iris away from the cornea, thus preventing the recurrence of the synechia.

If, after this procedure, an anterior synechia develops in the lower half of the graft, the first operation described can be carried out. I have had several cases thus treated successively with the two operations in which the eye remained without synechias, with clear transplant and good vision.

In these two operations, bacteria leading to endophthalmitis or panophthalmitis are often introduced into the eye. I have had several such instances, therefore the need for very aseptic technique and great care in performing these operations should be stressed. Prophylactic treatment with systemic application of penicillin should be carried out, beginning the day previous to the operation and continuing until all the signs of inflammation in the eye have disappeared. In addition, intravenous injections of typhoid vaccine should be instituted.

Infections

Conservative treatment may bring about successful cicatrization of ulcers of the graft when infection is not advanced. If the infection is more intense, more strenuous treatment, such as subconjunctival injection of penicillin (1 cc. of solution containing 10,000 units), is carried out. If the eye does not respond to penicillin therapy, subconjunctival injection of 1 cc. containing approximately 1 mgm. of streptomycin may be tried.

In these cases, in addition to the local treatment suggested, plus atropine and hot

applications, systemic treatment with penicillin or streptomycin should be carried out. Also, in order not to miss any possible way of improving the general condition of the patient, foreign-protein therapy by means of intravenous typhoid injections should be immediately started.

Penicillin combined with sulfadiazine, 4 gm. a day to maintain a blood level of 10 mgm. per cc., has been used with success when the penicillin alone did not seem to be effective. Iontophoresis with penicillin is apparently less effective than the subconjunctival injection of the same medication.

Cultures of the secretion or scrapings may be taken to decide which form of medication will be preferable, but treatment should be started without waiting for the result of the cultures.

In two cases, abscesses of the lens have been observed, both requiring removal of the lens when the abscesses were found to progress in spite of conservative treatment. In both cases the transplant became cloudy with extensive anterior synechias. In one the transplant cleared up with vision limited to fingers at three feet; in the other phthisis bulbi developed.

Glaucoma

Secondary glaucoma is another frequent complication following keratoplasy. In some cases, conservative treatment with miotics and hot applications will be successful. Others will require surgical treatment. If the glaucoma is of the congestive type, a very large iridectomy from the 10- to 2-o'clock positions is advisable. If the eye is not congested, it is preferable to perform a sclerectomy of the fistularizing type, such as an Elliot or Lagrange. If the glaucoma is associated with an anterior synechia, the glaucoma may be controlled by the excision of a large portion of the iris, including the synechia.

Vascularization

If at the 3rd or 4th week postoperatively, the transplant should begin to vascularize, the cornea adjacent to the vascularized area in the graft should be treated by radiation (about 1,500R), concentrating the treatments on the vascularized area alone, protecting the rest of the cornea with a lead filter. If the vascularization is permitted to develop over the whole graft, the transplant will most likely become very cloudy or opaque. However, I have observed some cases in which after vascularization the graft cleared up sufficiently to restore useful vision.

Inflammation

There are some cases in which the transplant has remained clear for 3 or 4 weeks and suddenly a mild uveitis develops which in a few days leads to cloudiness of the graft.

In some of these patients, careful examination will reveal a focus of infection and upon its removal the eye will immediately become quiet. Others will not show any improvement upon removal of the focus of infection. In these cases local treatment should immediately be started with atropine and hot applications as well as general treatment with penicillin and intravenous typhoid vaccine.

The general treatment must be instituted immediately, even before the possible cause of the uveitis is found. Some patients developing uveitis without an apparent focus of infection, but showing a low systemic resistance, respond well to intravenous injections of amino acids. Many of these patients are benefited by a high-vitamin diet or vitamin medication.

Corneal transplants, which after uveitis have become cloudy to the point where the patient could only see hand motion at one foot, have been improved in some cases to such an extent that it was impossible to tell at the end of a year that they had been nebulous, vision in some instances improving up to 20/30 and even 20/20.

Edema

After uveitis, epithelial edema and bullous degeneration of the epithelium are fre-

quently observed in the graft. This corneal edema is generally improved by applications from 3 to 6 times daily of sodium chloride hypertonic (15 percent) jelly. Occasionally after failure to clear up the edema, the scraping of the epithelium followed by very light superficial electrodesiccation has resulted in the disappearance of the edema but in permanent nebulosity of the graft, requiring further surgery. When the transplant remains nebulous or opaque without other intraocular complications, a 2nd, and sometimes a 3rd, transplant has been successful.

A corneal edema is frequently associated with endothelial edema, an entity that greatly resembles Fuchs's corneal dystrophy. In some cases, in spite of all treatment, the edema persists and the graft remains cloudy.

If the transplant cicatrizes with marked protrusion and opacity and if there is a synechia, the anterior synechia must be dealt with first, and when the cornea is free from the iris, a second corneal transplantation will be necessary.

Deformity

In cases of keratoconus, the transplant has often a tendency to protrude during the postoperative course. This must not be considered a complication but almost the normal cicatrization of the grafts in keratoconus. In order to obtain a more normal curvature, it is necessary to maintain a pressure dressing which is started approximately 14 days after the operation and is continued until the 5th or 6th postoperative week. Even in spite of the pressure dressing, the transplant, though transparent, sometimes cicatrizes with protrusion or uneven curvature, resulting in pronounced myopia and astigmatism, thus defeating the success of the operation. Contact lenses may help the situation occasionally; if not, a second transplantation will be necessary.

635 West 165th Street (32).

IV. PHYSIOPATHOLOGY

A. EDWARD MAUMENEE,* M.D., AND WALTER KORNBLUETH,† M.D.
Baltimore, Maryland

The fundamental problem in keratoplasty is the fate of the corneal graft. Do the donor cells in a homogenous graft continue to live after transplantation (as in autografts of the skin), or does the graft merely act as a framework for the ingrowth of the recipient cells? Until this basic problem is solved, the various factors which influence the final transparency of the graft cannot be properly evaluated. This report is based on an extensive experimental study which is still in progress, but has already yielded partial answers to these problems.

A number of studies have been made in the past to determine whether a corneal graft continues to live as autonomous tissue or if it merely acts as a reticulum for the ingrowth of cells from the recipient cornea. The conclusions reached in these investigations have been based on routine histologic studies of grafts at varying intervals following operation.

In most of the reported studies it is not mentioned whether the transplants were autogenous or homogenous grafts and, when the type of graft is specified, no distinction is made between the two. In general, most workers agree that Bowman's membrane, the corneal stromal fibers, and Descemet's membrane of the graft are not replacd.

There is, however, a wide difference of opinion on the fate of the corneal stromal cells. Salzer,[11] Bonnefon and Lacoste,[2]Loehlein[8] and others believe that the grafted corneal cells of the stroma die and are gradually replaced by similar cells from the recipient. Fuchs,[6] Imre,[7] Castroviejo[3] and others, on the other hand, think that the grafted corneal cells live and are not replaced by cells from the recipient, that is, the donor graft survives as a viable entity.

It may be pointed out that if the cells in homografts of cornea continue to live after grafting they are unique in this respect. Numerous studies of homografts of skin, bone, nerve, muscle, fat, and other tissue[1,2] have shown that the grafts are invariably replaced by cells from the recipient.

Exceptions to this are grafts from identical twins or mother to child which will occasionally live as autonomous tissue. Cartilage grafts at one time were also thought to be an exception to this rule. However, there is no definite proof that the donor cells of this tissue actually survive.

Medawar[9] has recently done some excellent studies on skin grafts in rabbits and has shown that the disintegration of the cells in homografts is the result of a hypersensitive reaction produced by the grafted cells of the donor animal. He has also shown that the rapidity of destruction of the cells in the homografts is proportional to the amount of tissue grafted. That is, if a large amount of skin is grafted, the cells will die in about 10 to 12 days; if one small graft is used, the cells will live for about 20 days.

In spite of the conclusive work done on skin grafts and other body tissues showing that homografts do not continue to live as autonomous tissues it is theoretically possible that corneal grafts may be an exception to this finding. The number of corneal stromal cells in a graft is small as compared to the number of cells in a skin graft, and the avascular cornea has been shown by

* From the Wilmer Ophthalmological Institute of The Johns Hopkins Hospital and University.
† (By invitation). Fellow of the Eye Bank for Sight Restoration, Inc., New York.

Chesney, Woods, and Campbell[4] and also Rich and Follis[10] not to develop the same immunologic reactions as do other tissues of the body in systemic infections of syphilis and Arthus phenomenon. It is, therefore, conceivable that corneal grafts may not produce a sensitivity reaction similar to that produced by skin grafts, and the cells may continue to live as they do in a tissue culture.

The Fate of the Grafted Cornea (Experimental)

In our experimental approach to this problem, it was necessary to have a clear understanding of the histologic pictures of a clear (successful) corneal graft and of an opaque (unsuccessful) graft. To determine this, we made histologic studies at almost daily intervals of autografts and homografts to clear corneas up to 2 weeks and at weekly and biweekly intervals up to 4 months. Rabbits were used as the experimental animal. A total of 38 autografts and 24 homografts have thus been examined histologically.

During the first week after operation, it is frequently difficult to predict accurately which grafts will eventually become opaque and which will clear. All grafts are cloudy to some degree during this time due to edema of the tissue. If there is no postoperative infection, if the edges of the graft are in good apposition with the recipient cornea, and if the edema of the graft subsides within a week to 10 days, the graft will usually clear. All grafts which were clear at 2 weeks after operation have remained clear for as long as they have been followed. In this study autografts and homografts of the cornea have given identical results in both clinical and histologic material. The following are the usual histologic patterns of clear and cloudy grafts.

Experiment 1

Clear grafts. During the first 48 hours after operation, the graft is loosely adherent to the recipient cornea by a fibrin clot. The epithelium from the recipient cornea grows into the cleft where it is not filled by a fibrin clot between the donor and recipient cornea (fig. 1). The epithelium is missing from the graft, the stroma is edematous and is invaded by a few polymorphonuclear cells. The endothelium is probably damaged physiologically in all cases and in some cases is actually denuded in areas.

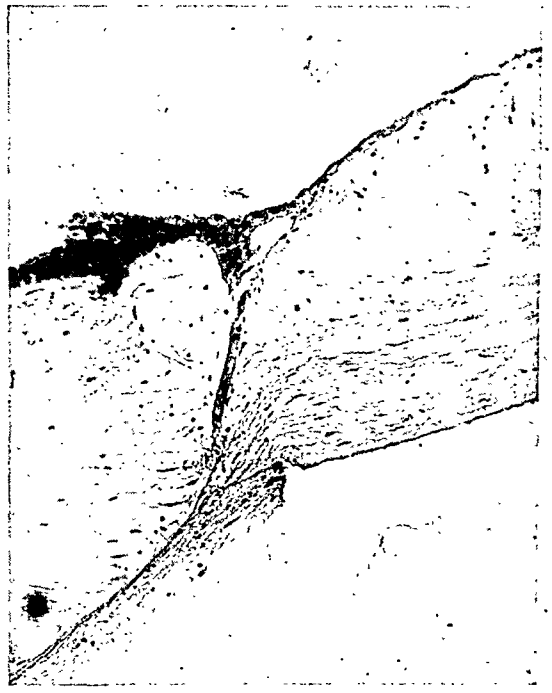

Fig. 1 (Maumenee and Kornblueth). Section of autogenous corneal graft (2 days after operation) showing ingrowth of epithelium and fibrin clot at site of operative wound. Migration of newly formed epithelium over wound and graft on right side. (H. & E. stain. ×100.)

During the next three days the epithelium is regenerated over the graft by migration from the recipient cornea. The edema of the stroma shows little change. A few wandering macrophages appear between the lamellae of the stroma. During this time the endothelial cells are usually replaced on the graft. It cannot be stated with certainty whether these cells are replaced by a proliferation of the remaining cells on the graft or by a migration of cells from the recipient cornea.

At 5 days after operation, a proliferation of cells that look like fibroblasts can be seen

Fig. 2 (Maumenee and Kornblueth). Section of autogenous corneal graft (5 days after operation) showing fibroblasts in wound. Graft on left. (H. & E. stain. ×100.)

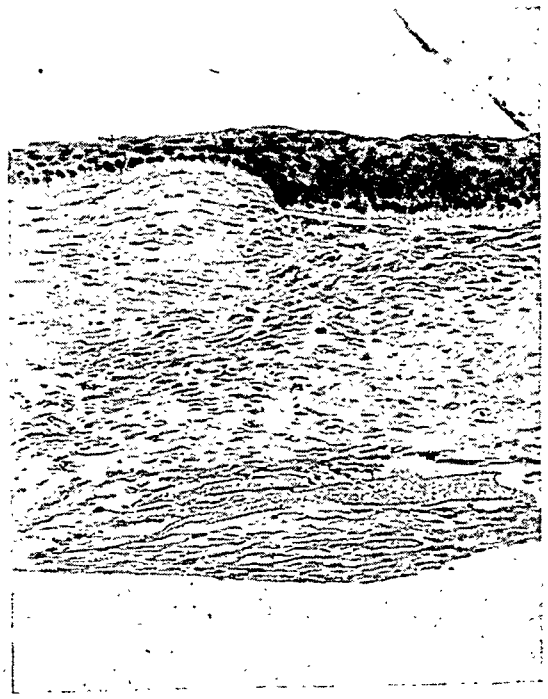

Fig. 3 (Maumenee and Kornblueth). Section of autogenous corneal graft (15 days after operation) showing ridge of fibroblasts on posterior surface of cornea. (H. & E. stain. ×100.)

in the wound and in the region of the endothelium on both the donor and recipient corneas (fig. 2). As these cells fill in the wound, the epithelial cells, which at first grew into the cleft, are destroyed. During the next 5 days, the edema of the stroma sub-

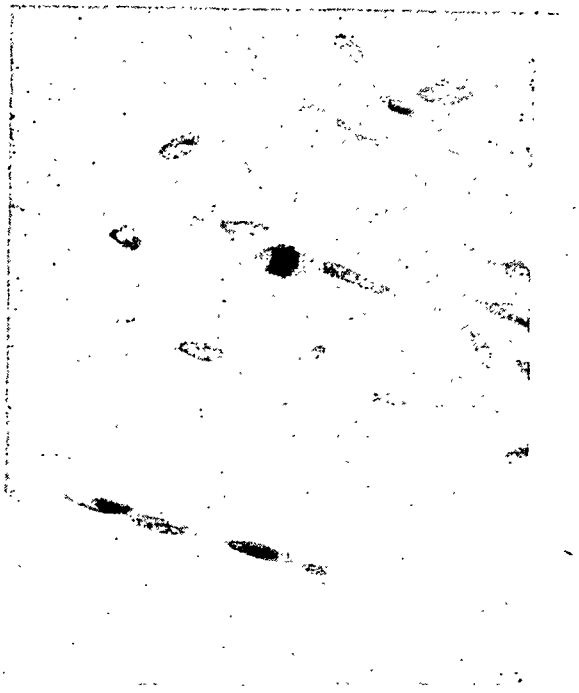

Fig. 4 (Maumenee and Kornblueth). Section of autogenous corneal graft (5 days after operation) showing mitosing keratoblast in metaphase in the corneal graft. (H. & E. stain. ×500.)

sides, the epithelium on the transplant assumes its normal structure, the fibroblasts increase in the wound and form a ridge of tissue on the posterior surface of the wound (fig. 3). During the first 2 weeks after operation, mitotic figures are occasionally observed in the stromal cells of the graft and in the stromal cells of the recipient cornea immediately adjacent to the graft (fig. 4). An exact explanation of this finding cannot be given at the present time but it does indicate that some reparative action is taking place in the graft as well as in the recipient cornea. During the 2nd and 3rd weeks fibrils appear in the scar and in the ridge on the posterior surface of the cornea. The graft assumes the normal corneal structure and cannot be differentiated from the normal recipient cornea (fig. 5). During the 2nd and 3rd months, the fibrils in the scar gradually assume the normal corneal pattern, and it is sometimes difficult to tell where the graft ends and the recipient cornea begins except for the slight irregularity of the lamellae and the break in Descemet's membrane (fig. 6).

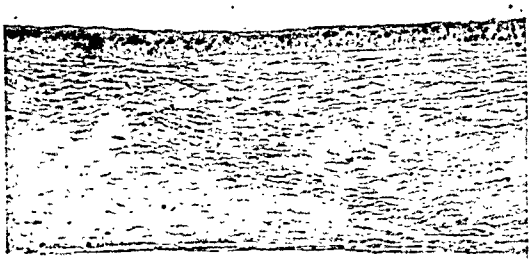

Fig. 6 (Maumenee and Kornblueth). Section of homogenous corneal graft (5 weeks after operation) showing healed wound between graft and recipient cornea. (H. & E. stain. ×100.)

Cloudy grafts. It is frequently impossible to predict which grafts will clear and which will become opaque, on either clinical or histologic examination during the first week after operation. However, wide gaps between the wound edges (fig. 7), massive anterior synechias (fig. 8), and infections of the suture tracts in the recipient corneas cause prolonged edema of the grafts. Grafts which remain edematous for 3 to 4 weeks frequently become partially opaque and, on histologic examination, are found to have several layers of fibroblasts with newly formed fibrils under the epithelium or endothelium (figs. 9 and 10).

Fig. 7 (Maumenee and Kornblueth). Section of autogenous corneal graft (15 days after operation) showing wide wound filled in with fibroblasts. (H. & E. stain. ×100.)

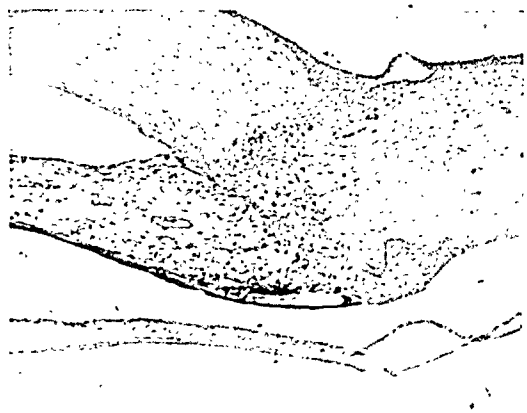

Fig. 8 (Maumenee and Kornblueth). Section of autogenous corneal graft (9 days after operation) showing massive anterior synechia with pigment-bearing cells in wound. (H. & E. stain. ×25.)

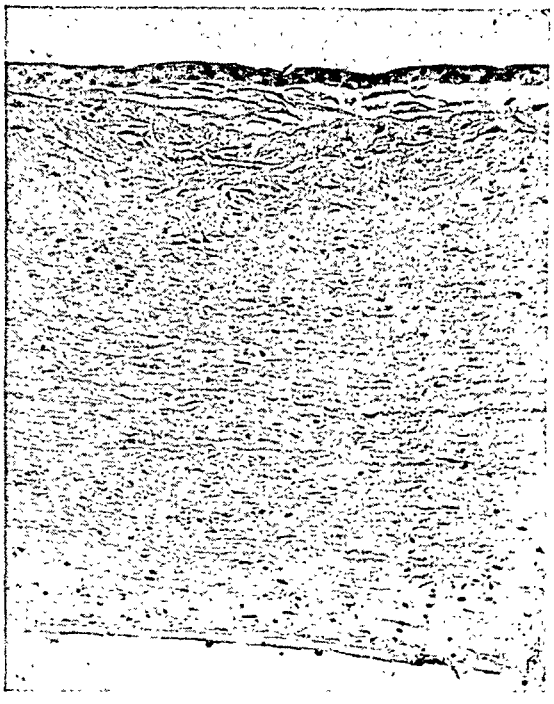

Fig. 9 (Maumenee and Kornblueth). Section of autogenous corneal graft (15 days after operation) showing early newly formed fibrous tissue beneath the epithelium. (H. & E. stain. ×100.)

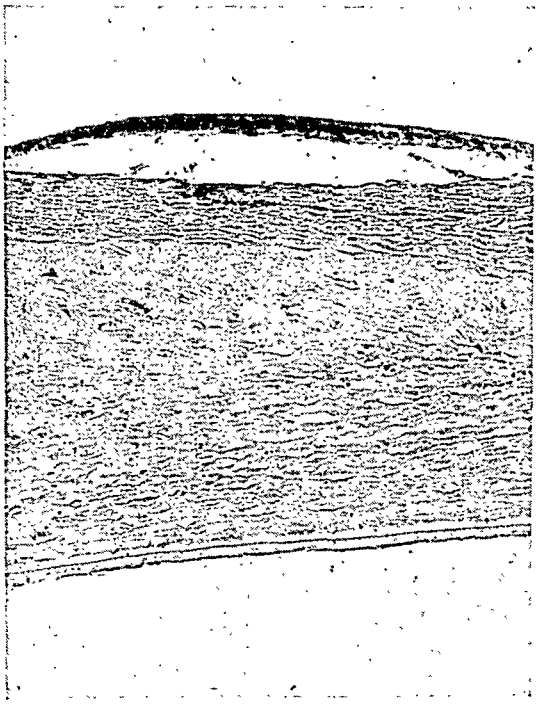

Fig. 10 (Maumenee and Kornblueth). Section of autogenous corneal graft (2 months after operation) showing newly formed fibrous tissue beneath the epithelium. (H. & E. stain. ×100.)

In grafts with greater edema the normal arrangement of the donor lamellae is destroyed in places with resultant opacities in these areas (fig. 11). In more severe reactions, from either unknown causes or low-grade infection, polymorphonuclear cells invade the stroma in greater numbers. There is a destruction of the lamellae of the graft and later an invasion of the graft by blood vessels, macrophages, and fibroblasts from the recipient animal. This latter type of re-

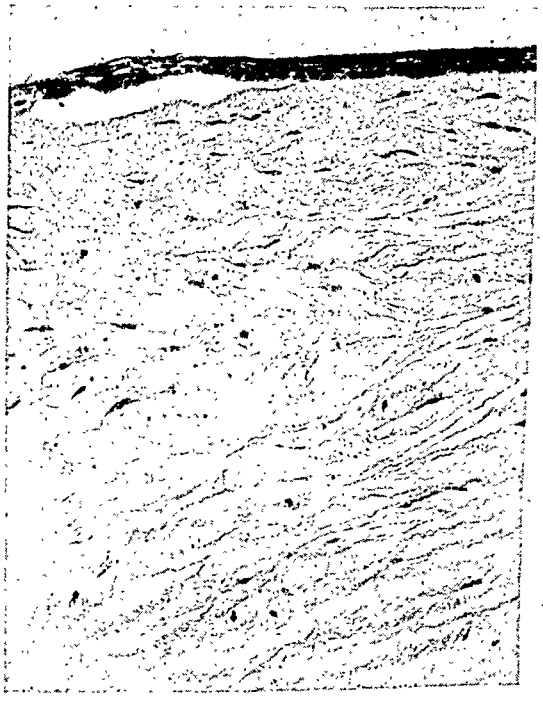

Fig. 11 (Maumenee and Kornblueth). Section of autogenous corneal graft (10 days after operation) showing massive edema of graft and irregular arrangements of lamellae. (H. & E. stain. ×100.)

action usually causes a dense opacification of the graft. During the early stages, these grafts look like granulation tissue and in the end stages resemble any dense scar of the cornea (fig. 12).

Routine histologic study did not show whether the stromal cells of either the autografts or homografts of the cornea were replaced by cells from the recipinet corneas or whether the grafts remained as viable entities. Against the supposition that the stromal cells were replaced by cells from the

recipient corneas was the fact that at no time were abnormal acellular areas seen or were any large number of dying or newly formed cells observed in the stroma of the autografts or homografts. It is possible, however, that a gradual replacement of the donor cells could have taken place and escaped detection on routine histologic examination.

Experiment 2

With this latter possibility in mind, studies were performed on regeneration of normal corneal stromal cells, in nongrafted corneas, to determine the origin of these newly formed stromal cells. These studies will be reported in detail elsewhere. In brief, the first group of experiments consisted in destroying the corneal cells by freezing various areas of the cornea to $-78°C.$ and studying the replacement of the cells in these areas.

It was found that the cells were replaced from uninjured keratocytes and wandering macrophages, but it could not be determined which of the newly formed cells arose from which precursor. We, therefore, sought some method of tagging the wandering macrophages so such precursors of the stromal cells could be identified in a regenerated corneal lesion.

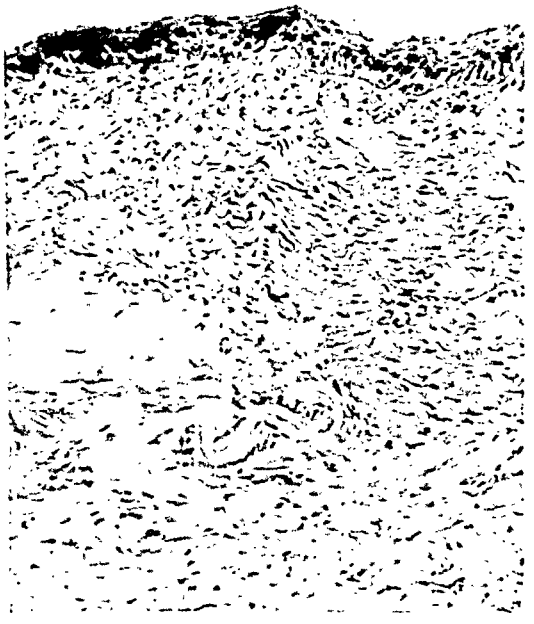

Fig. 12 (Maumenee and Kornblueth). Section of homogenous corneal graft (7 weeks after operation) showing replacement of stroma by fibrous tissue. (H. & E. stain. ×100.)

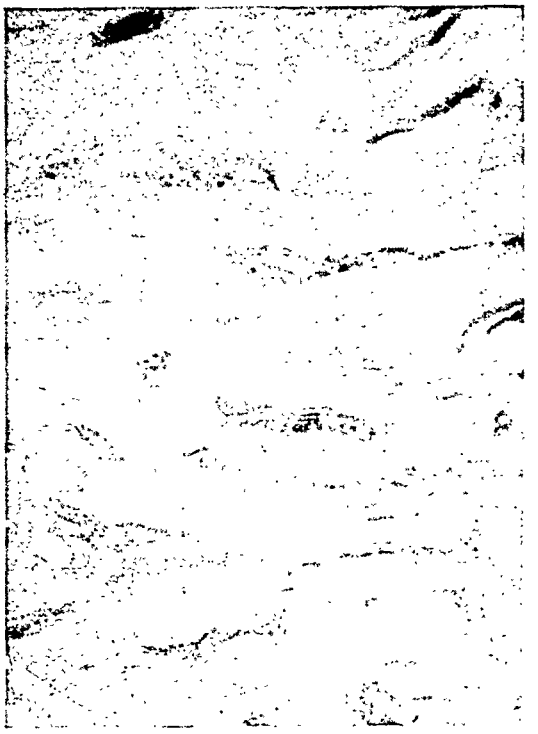

Fig. 13 (Maumenee and Kornblueth). Section of homogenous corneal graft to a rabbit saturated with trypan blue (15 days after operation) showing trypan blue in corneal corpuscles. (Lithium-carmine stain. ×750.)

To this end, animals were saturated with trypan blue systemically and areas of their corneas were frozen. In such animals the macrophages can be identified by the presence of trypan blue granules in their cytoplasm. These "tagged" cells were found in great numbers in the regenerating cornea.

With the fact established that wandering macrophages participate in the regeneration of dead corneal tissue, the following experiment was performed.

Grafts were done on animals saturated with trypan blue. When these grafts were examined histologically, trypan blue could be found in a few of the stromal cells in the autogenous and homogenous grafts. The

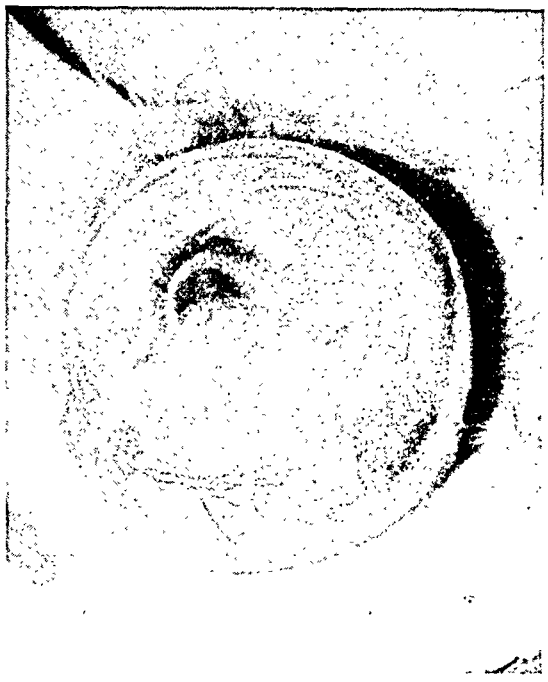

Fig. 14 (Maumenee and Kornblueth). Partially clear formalin corneal graft 7 months after operation.

number of stromal cells containing trypan blue were much greater in cloudy than in clear grafts (fig. 13). This clearly indicated that at least to some extent the wandering macrophages of the recipient corneas participate in the regeneration of the cells in the donor grafts.

EXPERIMENT 3

The question of the replacement of the corneal stromal cells were studied by another method. Scherschewskaya[13] has stated that clear corneal grafts can be obtained from formalized donor corneas. If this is true, all of the cells in an ultimately clear graft of this type must be derived from the recipient animal because the cells in the donor graft are killed when this tissue is placed in formalin. We have been unable to confirm Scherschewskaya's reported finding that clear transplants can be obtained with formalized corneas. Fifteen such grafts have been performed and in only one instance was a partially clear graft obtained (fig. 14).

A somewhat similar experiment on this same line was likewise unsuccessful. In this experiment the cells of the donor cornea were killed by freezing the tissue. In 13 attempts no clear grafts were obtained. Many of these grafts of frozen tissue looked as promising as did fresh grafts for 5 to 7 days after operation. However, all became progressively more edematous after removing sutures and frequently the anterior lamellae sloughed off during the first 2 weeks after operation.

In short, all efforts to obtain a clear graft by the use of nonviable corneas in which the cells have been killed either by formalin or by freezing have been completely unsuccessful. These experiments would indicate that viable corneal tissue is essential for a successful graft. It is possible, however, that the denaturization of the corneal protein by the formalin, or disturbance of the cohesion of the stromal lamellae by freezing may have influenced these results.

These experiments do not entirely contradict Filatov's[5] recent statement that he obtained 66.6 percent successful grafts when he used corneas preserved for 1 to 3 days at + 2° to + 4°C. and only 24.1 percent successful grafts when he used fresh corneas. Bajenova[1] demonstrated that corneas preserved in moist chambers at +2°C. for 10 days contained viable stromal cells which would grow in tissue culture. We can offer no explanation, however, why Filatov should obtain better results with preserved but viable tissue than with fresh tissue.

These three experiments just reported in brief indicate that living donor stromal cells are essential at least during the first stages of a graft for its final clarity.

EXPERIMENT 4

A fourth experiment was done with the idea of determining at what time the viable donor stromal cells were no longer essential for the continued clarity of the graft. To this end, a series of autografts and homografts were made in experimental rabbits, and at varying times after the operation. The cells of the donor graft were killed by the freezing

technique. It was found that the donor cells could be completely destroyed as early as 11 days after operation and the graft would regain its normal clarity after the edema following the injury subsided (fig. 15).

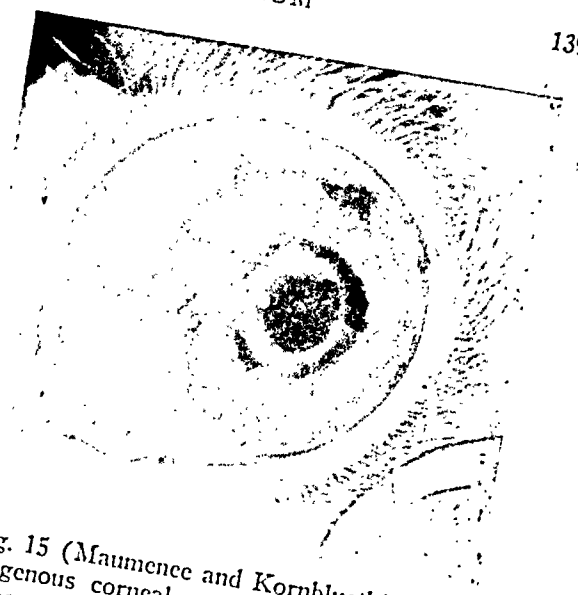

Fig. 15 (Maumenee and Kornblueth). Clear homogenous corneal graft in which all cells had been destroyed in the graft by freezing 11 days after operation. Picture taken 4 weeks after freezing.

These four experiments do not give a conclusive answer to the fate of the stromal cells in a corneal graft. They do, however, give us a clear indication of the general picture. First, there is no massive replacement of the cells in an autogenous or homogenous graft at any one time. Second, the wandering macrophages of the recipient animal probably contribute from the beginning in a limited degree to the replacement of the donor cells in a corneal graft.Third, viable donor cells are essential for a successful take of a transplant, at least for the first 2 weeks after operation, until the dependence of the donor graft on the recipient cornea is fully established. The donor cells are not essential to the clarity of the graft once the tissue has become firmly attached to the recipient cornea.

This is the apparent picture as well as it can be visualized from the information so far at hand. It is quite possible that further investigation may alter this concept of the process. The final answer of the fate of the donor stromal cells cannot be decided until a method is obtained to tag the donor corneal cells or both the corneal cells and the wander macrophages of the recipient.

Factors which influence the result of keratoplasty

Most of the factors which determine the final clarity or cloudiness of a corneal transplant have been observed clinically. These factors may be divided into three groups: the condition of the grafted tissue, the status of the recipient cornea, and the operative complications. From the experimental standpoint we can add the following observations.

1. Fresh living corneal tissue is the most favorable material for grafting. Nonviable grafts are completely unsatisfactory.
2. Excessive trauma either in removing or handling the graft is detrimental to the final clarity of the tissue.
3. Numerous small vessels in the recipient cornea do not appear to influence the result of keratoplasty to any marked extent. This is illustrated by the following experiment. A group of animals with vascularized corneas and small central corneal leukomas have been subjected to autografts and homografts. The recipient animals had been previously grafted and the transplants had become opaque and vascularized (fig. 16). The reaction following the initial graftings was allowed to subside before regrafting. In this group the percentage of clear grafts obtained on the second attempt was the same as when animals with normal corneas were used. This indicates that numerous small blood vessels in the cornea without other damage to the tissue are not detrimental to the final clarity of the graft.
4. Dense and diffuse corneal opacities influence the results of operation unfavorably. This is shown by the following experiment.

A group of animals in which dense corneal opacities had been produced by the injection of 20th-normal sodium hydroxide into the lamellae of the corneas were subjected to keratoplasty. If the grafts on these animals

Fig. 16 (Maumenee and Kornblueth). Opaque autogenous corneal graft with vascularization (2 months after operation). This eye used for regrafting.

Fig. 17 (Maumenee and Kornblueth). Clear homogenous corneal graft 5½ weeks after operation. The cells in the recipient cornea had been destroyed by freezing 3 weeks before operation.

were surrounded by the opacities the transplants always become opaque. However, if the opacity in the recipient cornea was present on only one or two sides of the graft, the transplant would occasionally remain clear.

The reason why corneal grafts fail to remain clear in completely opaque corneas is not fully understood. One explanation which has been given for the poor results in this type of cornea has been that there are not enough normal corneal cells surrounding the graft. This explanation is probably not correct, however, for clear transplants can be obtained in corneas in which all of the original cells have been destroyed by freezing if sufficient time is given for the edema of the cornea to subside and new cells to grow in (fig. 17).

While we do not have a satisfactory explanation for the poor results in opaque corneas, it is interesting that the grafts are frequently edematous for several weeks before they finally become scarred and vascularized when they are inserted into corneas damaged by sodium hydroxide.

5. The operative complications such as poor apposition of the wound edges, anterior displacement of the graft, and secondary infection are essentially the same in experimental animals as in clinical cases. Small anterior synechias are unfavorable but do not always cause an opacification of graft.

SUMMARY

Finally, how can one visualize the course of events in a successful graft? The donor cornea should be viable tissue and as untraumatized as possible. The continued viability of the graft is not essential after the second postoperative week. The recipient cornea should not be completely opaque and should not be edematous.

Small blood vessels in the recipient cornea are not detrimental to the final clarity of the transplant. Good apposition of the graft should be obtained at operation. After the graft has been inserted, it becomes edematous during the first 24 hours and the epithelium is lost. The endothelium is always

damaged to some extent but part of it may remain on the graft.

The majority of the stromal cells continue to live in the graft and do not show a massive degeneration or replacement at any time during the postoperative course. They are supplemented, at least to a limited extent, by the newly formed keratoblasts from the recipients macrophages.

The epithelium is replaced by a migration of epithelium from the recipient cornea. The endothelium may be repaired from the uninjured cells of the graft or a migration of cells from the recipient cornea. The wound is closed at first by a fibrin clot and later by fibroblasts which form fibrous tissue between the graft and adjacent cornea.

V. RESULTS*

WILLIAM COUNCILMAN OWENS, M.D.,† JOSEPH J. FRANK, M.D., BRENDAN LEAHEY, M.D., PAUL E. MESSIER, M.D., HAROLD G. SCHEIE, M.D., B. RICHARD VINCENT, M.D., JOSEPH A. C. WADSWORTH, M.D., AND FREDERICK C. STANSBURY, M.D.

The literature on corneal transplant operations contains few statistical facts on the final results of this well-publicized surgical procedure. One of the chief difficulties in obtaining such data has been the lack of a sufficiently large number of cases in any one clinic to permit statistical analysis.

To overcome this difficulty the American Academy of Ophthalmology and Otolaryngology made arrangements for a group of clinics to pool their material, for it was thought that the combined data would be sufficiently large to analyze statistically.

Clinics in closely neighboring cities were chosen for the study so that the doctors from each of the participating clinics could easily meet from time to time for discussions. The Massachusetts Eye and Ear Infirmary, the Institute of Ophthalmology of the Presbyterian Hospital, the Manhattan Eye, Ear, and Throat Hospital, the New York Eye and Ear Infirmary, the New York Hospital, the Hospital of the University of Pennsylvania, and the Wilmer Institute of The Johns Hopkins Hospital were chosen to participate.

A standardized tally sheet for the analysis of the cases was drawn up by the group of doctors. Each of the representatives from the coöperating institutions studied the histories from his own hospital, and recorded the pertinent data on the standardized tally sheets. The sheets from all the hospitals were collected. The data were transcribed to punch cards and analyzed with the aid of automatic sorting and counting machines. After the data were gathered, the representatives from the participating hospitals met to discuss the results and to draft plans for this report.

This plan for statistical study of the corneal transplant operation has worked very well. The pooling of opinions has been beneficial, but the greatest advantage is that the plan provides a standardized method of analysis for a large number of cases from many separate clinics.

Without it, each clinic would have reported its individual experience. The analysis of the data probably would have been different in each report and comparison of the results of one clinic with those of another would have been difficult. We feel that the American Academy should continue to sponsor and guide similar coöperative clinical studies on other subjects.

We were able to gather data on 417 corneal transplant operations performed at the various coöperating hospitals. The analysis of this material forms the basis of the following report.

RESULTS ACCORDING TO CLARITY OF GRAFT

In 16 of the 417 cases, there was no statement in the history as to the final clarity of the graft. In addition, 20 of the cases had

* From the Wilmer Ophthalmological Institute of The Johns Hopkins Hospital and University, Baltimore; the Manhattan Eye, Ear, and Throat Hospital, New York; the Massachusetts Eye and Ear Infirmary, Boston; the New York Hospital, New York; the Hospital of the University of Pennsylvania, Philadelphia; the New York Eye and Ear Infirmary, New York, and the Institute of Ophthalmology of the Presbyterian Hospital, New York.

† Baltimore, Maryland.

been followed for only 3 months or less. In 242 or 63.5 percent of the 381 remaining cases, the graft became cloudy, and in 139 or 36.5 percent, the graft remained clear. Therefore, in the group as a whole without selection of cases, there was approximately one chance in three that the graft would remain clear.

Selection of cases

In order to determine whether it is possible to increase the chances of obtaining a clear graft by proper selection of the cases, we analyzed the effect of various factors on the final clarity of the graft. The cases were divided into groups and the percentage of grafts remaining clear was compared in each of the groups.

TABLE 1

Relationship of diagnosis to percentage of clear grafts

Diagnosis	No. of Cases	Clear Grafts Followed 4 Mos. or more
Conical cornea	63	65.2%
Hereditary dystrophy	17	58.8%
Scar luetic interstitial keratitis	49	49.0%
Scar nonspecific inflammatory	141	46.9%
Active keratitis or ulcer	13	23.1%
Scar chemical	24	20.8%
Scar traumatic	22	18.2%
Scar gonococcal	23	8.7%
Fuchs' dystrophy	10	0
Total	362	36.5%

Age of patient. The youngest patient in our series was 3 years of age and the oldest was 80 years. However, no correlation was found between the percentage of grafts remaining clear and the age of the patient.

Diagnosis. Table 1 shows the classification of the cases according to diagnosis. The cases with conical cornea obtained the highest percentage of clear grafts. In about 2 out of 3 cases of conical cornea the graft remained clear. The results in the cases with hereditary corneal dystrophies (Groenouw, Haab-Dimmer, and Fleischer types) were almost as good, 58.8 percent of the transplants remaining clear. In the cases with corneal scars from luetic interstitial keratitis or from other nonspecific corneal inflammations, about half of the transplants remained clear. In contrast, the results in cases with corneal scars from chemical burns, trauma, or gonococcal ulcers were poor, only about one transplant in 5 or 10 remaining clear. Total failure resulted in every instance in cases with Fuchs's dystrophy of the cornea. The 13 cases in which a corneal transplant operation had been performed in the presence of an active keratitis or an active ulcer are interesting. In these, it was surprising to find that the transplant remained clear in 23.1 percent of the cases, a result that would not have been expected.

Previous operations. In 30 of the cases, the corneal transplant operation had been performed on eyes that had previously had one unsuccessful corneal grafting. In 8 or 21.2 percent of these the second graft remained clear. In an additional 11 cases, two previous corneal transplant operations had resulted in failure and a third graft was performed. In only 1 of these cases did the third graft remain clear.

There is general agreement that corneal grafting is technically more difficult in aphakic eyes than in eyes with the lens in place. In our series corneal transplant operations were done in 7 cases with aphakia. The results were good; in 3 cases (42.8 percent) the graft remained clear.

The chances for obtaining a clear graft were reduced in all the cases in which previous operations such as iridectomies, filtering operations, superficial keratectomies, or cauterization of the cornea had been performed. Eight cases had previously had a conjunctival flap drawn over the cornea, and in none of them did the transplanted cornea remain clear. Undoubtedly the eyes requiring other operations before the corneal

grafting had severe defects, and a poor prognosis was to be expected.

Size of corneal opacity. The cases were divided into four groups according to the extent of the corneal opacity. Table 2 shows

TABLE 2

RELATIONSHIP OF SIZE OF CORNEAL OPACITY TO PERCENTAGE OF CLEAR GRAFTS

Size of Opacity	No. of Cases	Clear Grafts Followed 4 Mos. or More
None	16	50.0%
Central	104	52.8%
One half or less	74	29.8%
Over one half	173	27.7%

that the cases with no corneal opacity or those with only a central corneal opacity had the best prognosis. In approximately half of these cases the grafts remained clear, while only about 1 case in 3 or 4 with more extensive opacities obtained a clear graft. It is often difficult to estimate the depth of the opacity, especially in cases with extensive corneal scarring. Therefore, in classifying our cases according to the size of the opacity, we did not include a consideration of the depth of the opacity.

TABLE 3

RELATIONSHIP OF CORNEAL VASCULARIZATION TO PERCENTAGE OF CLEAR GRAFTS

Vascularization of Cornea	No. of Cases	Clear Grafts Followed 4 Mos. or More
None	170	50.5%
Slight	52	50.0%
Moderate	71	25.4%
Extensive	64	10.8%

Vascularization of the cornea. Table 3 shows the percentage of clear grafts obtained in our series when the cases were grouped according to the extent of the preoperative corneal vascularization. About one half of the cases with no vascularization or with only "slight" vascularization obtained clear grafts. On the other hand, only a fourth of those cases with "moderate" vascularization obtained a clear graft. When the corneal vascularization had been estimated as being "extensive," only about 1 case in 10 obtained a clear graft.

Anterior synechias. The presence of anterior synechias is one of the most difficult problems in handling a case for corneal grafting. In some of our cases, attempts had been made to eliminate the anterior synechias before the corneal transplant operation was undertaken. In many cases, these attempts were unsuccessful. Thirty-nine cases in our series had corneal grafting in the presence of anterior synechias. In only 6 or 15.4 percent of these did the corneal graft remain clear.

General prognosis. In most of the cases, the factors we have just considered separately were not isolated. For example, patients with keratoconus often had no corneal opacity or only a central one. In addition they usually had no vascularization of the cornea, no anterior synechias, and had had no previous surgery. On the other hand, patients with opacities due to burns or gonococcal ulcers usually had extensive corneal opacities and vascularization, broad anterior synechias, and frequently numerous operations had been performed on the cornea before the transplant operation had been undertaken.

TABLE 4

RELATIONSHIP OF PROGNOSIS TO PERCENTAGE OF CLEAR GRAFTS

Prognosis	No. of Cases	Clear Grafts Followed 4 Mos. or More
Very good	79	68.3%
Less good	115	50.5%
Unfavorable	99	12.1%
Contraindicated	38	10.5%

However, in order to arrive at a decision as to the results of corneal grafting in specific types of cases, we divided our cases into four categories using the criteria for

prognosis described by Castroviejo.* (See table 4.)

Group 1. The first group of very favorable cases comprised cases of keratoconus, cases with only a central corneal opacity, and cases of mild interstitial keratitis. Of the 79 cases in this group, 54 or 68.3 percent obtained clear grafts.

Group 2. The second group of less favorable cases comprised cases of hereditary corneal dystrophy (Fleischer, Haab-Dimmer, Groenouw, and Salzmann types), cases with extensive superficial corneal opacities without vascularization, cases with superficial tear-gas burns without pannus, cases with adherent leukomas, cases with central descemetocele, and cases with extensive interstitial keratitis. Of the 115 cases in this group, 58 or 50.5 percent obtained clear grafts.

Group 3. The third group of unfavorable cases included cases of corneal scarring involving the limbal and pupillary area, extensive deep leukomas, band-shaped degeneration of the cornea, dystrophia adiposa, aphakic cases, and cases of extensive opacities with vascularized pannus. Of the 99 cases in this group, 12 or 12.1 percent obtained clear grafts.

Group 4. The fourth group of cases in which corneal transplantation was considered contraindicated included cases with Fuchs's dystrophy, cases with extensive corneal opacities with calcareous degenerations, cases with corneal opacities of pemphigus, and those of corneal opacities with extensive anterior synechias. Of the 38 cases in this group, 4, or 10.5 percent, obtained clear grafts. Statistically there was no difference in the results between the cases in Group 3 and those in Group 4.

In summary, in the first small group of selected cases, with the best prognosis, about two thirds of the grafts remained clear. In the second large group of less favorable cases, one half of the grafts remained clear, while in the last two groups of unfavorable cases, there was only one chance in eight of obtaining a clear graft.

Visual results

Ideally, the most important consideration in evaluating the corneal transplant operation would be the improvement in vision that results from the operation. However, mere comparison of the preoperative and postoperative vision is inadequate, for some cases with clear grafts must be eliminated from consideration because of extraneous causes for poor vision. For example, cases with preoperative cataract, glaucoma, nystagmus, or amblyopia ex anopsia must be discarded even though the grafts remain clear. The significance of minor improvements in vision must also be carefully evaluated. In some of the cases a small improvement in vision may be recorded and the case classified as having improved vision postoperatively. For example the preoperative vision might have been recorded as 5/200, and the postoperative vision as 15/200.

This may not represent a true improvement in vision. Certainly the examiner spends a good deal more time and effort coaxing the patient to read the chart after operation than he does before the operation was performed.

In addition, by repeated examination, the patient often becomes familiar with the blurred form of the 20/200 letter. He learns to interpret the blurred image more readily by experience and may therefore show an apparent improvement in vision, not as a result of the operation, but only as a result of frequent testing.

Although ideally the improvement in vision should be the best criterion for the success of the operation, practically it is difficult to assess statistically since it must be qualified so carefully. For these reasons, we have correlated most of our data with the

final anatomic result, that is, the presence or absence of a clear graft. However, it is important for a complete picture to include some of the data we found on the visual acuity, if we remember the limitations of such a study.

Table 5 shows the relationship between the preoperative and postoperative vision in 253 of the cases. As mentioned before, we had to exclude cases with preoperative cataracts, glaucoma, nystagmus, or amblyopia ex anopsia, and those in which some disease was found in the posterior segment of the eye.

TABLE 5

RELATIONSHIP OF PREOPERATIVE VISION TO POSTOPERATIVE VISION

Postoperative Vision \ *Preoperative Vision*	LP	HM	1–10/200	11–20/200	20/100	20/70	20/50	20/40	Total
No LP	6	6	10		1				23
LP	10	10	14	2	2		1		39
HM	2	20	18	2	1				43
1–10/200	2	6	21	4	1	3			37
11–20/200	2	2	5	4	3			1	17
20/100		1	9	4					14
20/70	2	3	8	2		3			18
20/50	1	6	6	3					16
20/40		3	8	4	1	1			17
20/30		1	14		1	1	1		18
20/20		1	7		1	2			11
Total	25	59	120	25	11	10	2	1	253

In Table 5, the numbers in the heavy squares refer to cases that had the same category of vision postoperatively and preoperatively. The numbers above the heavy squares refer to cases that fell into a category of poorer postoperative vision, and the numbers below the heavy squares refer to cases that fell into a category of better vision postoperatively than preoperatively.

A final visual acuity of 20/30 to 20/20 was obtained in only 29 or 11.4 percent of the cases, and in 23 or 9.1 percent of the cases all light perception was lost as a result of the corneal transplant operation.

The visual result in the cases grouped according to general prognosis was interesting. In the cases with the best prognosis (group 1), limited to cases of keratoconus, cases with only a central corneal opacity, and cases of mild interstitial keratitis, 58 cases had preoperative vision of 20/200 or less, Of these, 32 cases or 55.2 percent attained a final vision of 20/100 or better.

Of the cases with a less favorable prognosis (group 2) 74 had preoperative vision of 20/200 or less, and 39 or 52.7 percent of these obtained a final vision of 20/100 or better. Of the cases with an unfavorable prognosis or those in which the operation seemed contraindicated (groups 3 and 4) 7 out of a total of 64 or 10.9 percent were raised from a preoperative vision of 20/200 or less to a postoperative vision of 20/100 or better. Of the 229 cases with a preoperative vision of 20/200 or less, 83 or 36.2 percent obtained a postoperative vision of

20/100 or better, approximately 1 case in 3.

The final visual results in the 24 cases with initial vision of 20/100 or better deserve careful consideration. Only 6 of these cases obtained a final vision of 20/30 or better, while in 13 of these cases the final vision was reduced to 20/200 or less. Therefore, while only a fourth of these patients with relatively good preoperative vision obtained a vision of 20/30 or better, over half of them had their vision reduced to 20/200 or less as a result of the operation.

Although the number of cases is small, these figures indicate that it is probably unwise to perform a corneal transplant operation on an eye with a corrected visual acuity of 20/100 or better.

Conclusions

1. A statistical study has been made of the results of 417 corneal transplant operations.

2. The graft remained clear in 36.5 percent of the cases.

3. The percentage of clear grafts varied greatly with the cause of the corneal opacity. The best results were obtained in cases of keratoconus (65.2 percent), hereditary dystrophy (58.8 percent), interstitial keratitis (49.0 percent), and nonspecific inflammatory scars (46.9 percent). Poor results were obtained in cases with active keratitis or corneal ulcer (23.1 percent), scars from chemical burns (20.8 percent), trauma (18.2 percent), or gonococcal ulcers (8.7 percent). No clear grafts were obtained in cases with Fuchs's dystrophy.

4. The larger the size of the corneal opacity and the greater the extent of corneal vascularization, the less were the chances of obtaining a clear graft.

5. In a group of 79 cases selected as having the most favorable prognosis, 68.3 percent of the grafts remained clear.

6. Of 229 cases with preoperative vision of 20/200 or less, 36.2 percent obtained a postoperative vision of 20/100 or better. A group of 58 cases with preoperative vision of 20/200 or less was selected as having the most favorable prognosis. Of these cases, 55.2 percent obtained a postoperative vision of 20/100 or better.

7. The visual results after corneal transplantations in patients with preoperative vision of 20/100 or better do not warrant the risk of the operation.

THE RESPIRATION OF THE STORED CORNEA*

T. D. DUANE, M.D.
Iowa City, Iowa

INTRODUCTION

A better understanding of certain physiologic processes that take place in corneas which are "stored" under various conditions may be gained by measurements of the respiration of the tissue. This method may aid in determining the optimum conditions for preservation of the donor cornea. A number of methods for preservation have been described but most reliable and thorough reports are based on four different techniques for storage, namely: (1) over Ringer's solution in air at 4°C.;[1,2] (2) under oil;[3,4] (3) in formalin;[5,6] (4) at subzero centigrade temperatures.[8,9] A study of the respiratory metabolism changes under these conditions is obviously important.

METHODS

Bovine eyes were used exclusively in this experiment since they were readily available.† The QO_2 of the beef cornea is approximately the same as the human cornea[10] and other mammalian corneas.[11]

On enucleation at the packing plant entire eyes were stored as follows: (1) at 4°C. suspended over Ringer's solution contained in a large sealed thermos jug; (2) under mineral oil at 15°C. The corneas from these eyes were removed at the time of the metabolism studies.

Isolated corneas from freshly enucleated eyes were stored as follows: (1) in commercial formalin (5 percent and 35 percent); (2) in the deep freeze at −40°C.; (3) at −40°C. after quick freezing on the expansion chamber of the carbon dioxide frozen section apparatus. The latter two groups were permitted to thaw immediately prior to being placed in the Warburg flasks.

All investigations of respiratory metabolism were made according to the standard Barcroft-Warburg technique. Each cornea was divided into four segments of approximately equal size before being placed in the Warburg flask containing a Ringer-phosphate buffer with 0- to 2-percent glucose.[12] Manometric readings were made at frequent intervals during 2- to 6-hour periods. The oxygen consumption for each interval was computed in terms of dry tissue weights. From this data a curve was plotted to show the oxygen consumption of each cornea and individual QO_2 values were determined. From these values the average QO_2 for an experimental group was calculated.

RESULTS

1. + 4°C. storage. Over 100 intact eyes were stored by this method. It was found

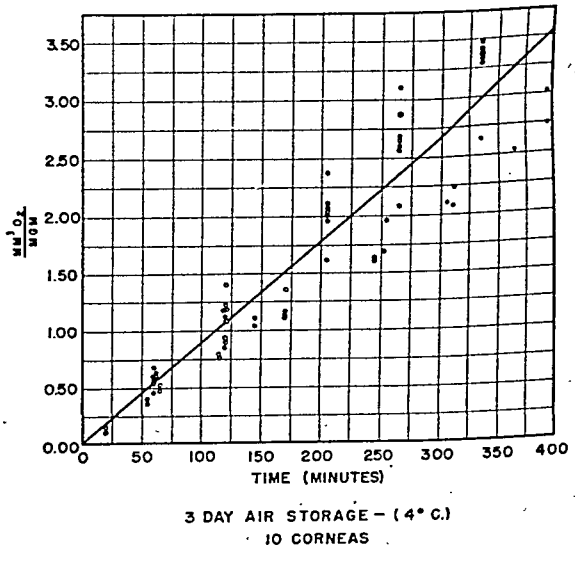

Fig. 1 (Duane). Respiration of 10 corneas from intact eyes stored for three days over Ringer's solution at +4°C. Ordinate: mm.³ O_2 per mgm. dry weight. Abscissa: minutes.

* From the Departments of Physiology and Ophthalmology, Medical Laboratories, State University of Iowa.

† Eyes obtained through courtesy of Gay's Locker, Iowa City, Iowa, and Wilson Company, Cedar Rapids, Iowa.

that if they were removed from the low temperature during the first seven days of storage the corneas respired normally. Figure 1 is a sample curve which shows the data obtained from corneas stored for three days demonstrating that the normal rate of respiration is still present. After seven days the respiration began to fall off (fig. 2). By the tenth day bacterial contamination precluded further investigations.

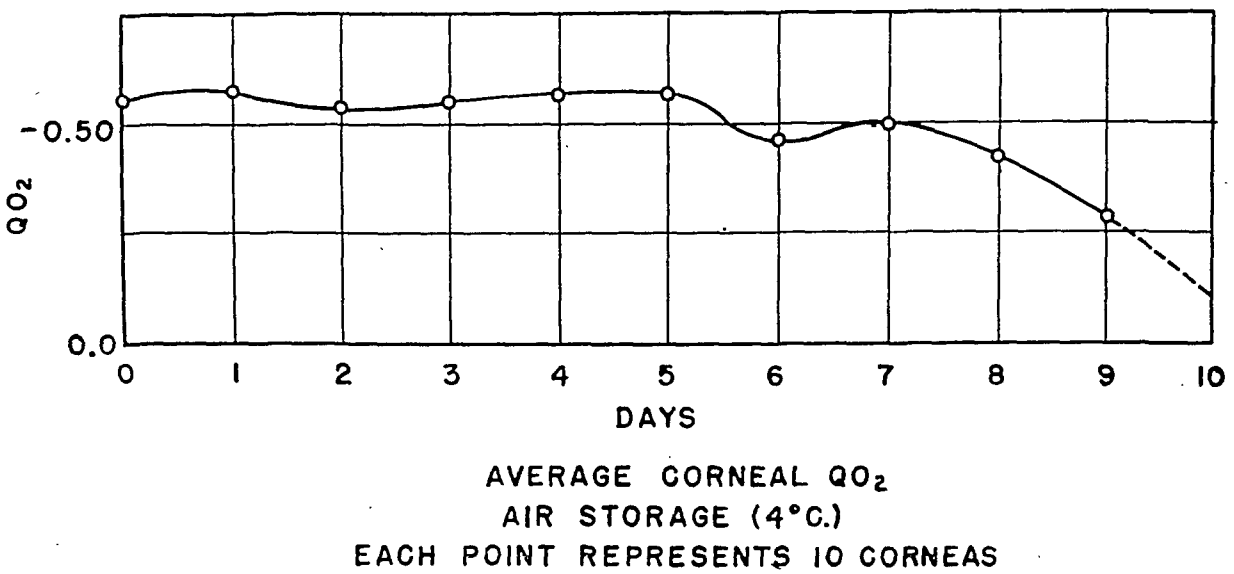

Fig. 2 (Duane). Average QO_2 of corneas from intact eyes stored over Ringer's solution at +4°C. Each point represents 10 corneas.

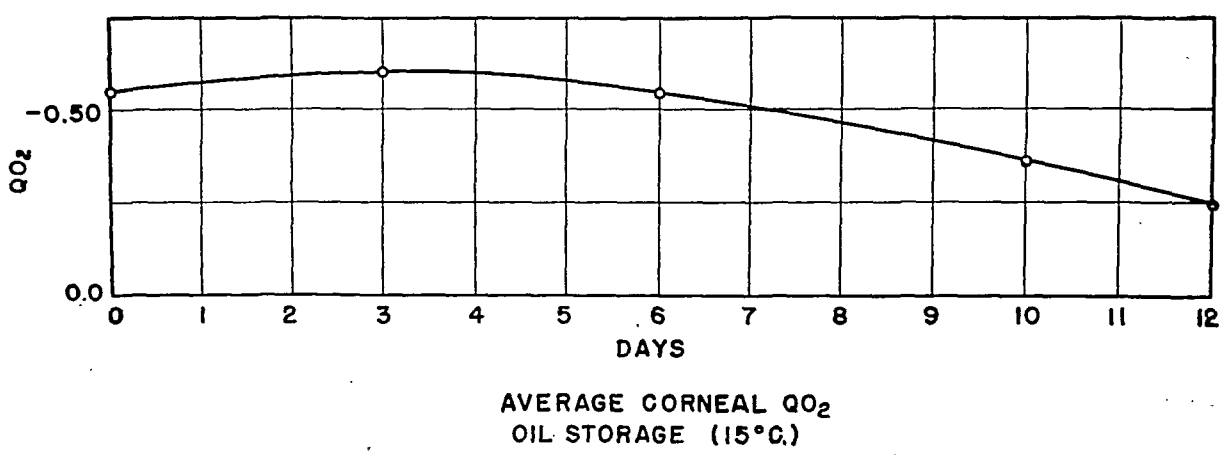

Fig. 3 (Duane). Average QO_2 of corneas from intact eyes stored under oil at +15°C.

2. Storage under oil. Sixteen corneas were studied after a storage period from 3 to 12 days. The results shown in Figure 3 are similar to those found for corneas stored at +4°C. In these experiments also bacterial contamination prevented longer storage periods.

3. Formalin storage. The 11 corneas included in this group did not respire when placed in the manometric flasks. Merely dipping the cornea in either 5-percent or 35-percent formalin completely inhibited the respiration. No respiration appeared after longer storage in these fluids when followed up to four days.

4. Deep freeze, —40°C. Results ob-

tained from 22 corneas in this group are plotted in Figure 4. The QO_2 dropped to one-half normal in 24 hours and within four days had fallen to one-fifth normal where the cornea. However, the reproducibility of the curves presented in this report is evidence of their reliability. Even when the corneal respiration is depressed by low temperatures, readings are obtained which can be plotted upon a straight line. A typical curve, Figure 6, is offered as evidence of the feasibility of this technique in these studies.

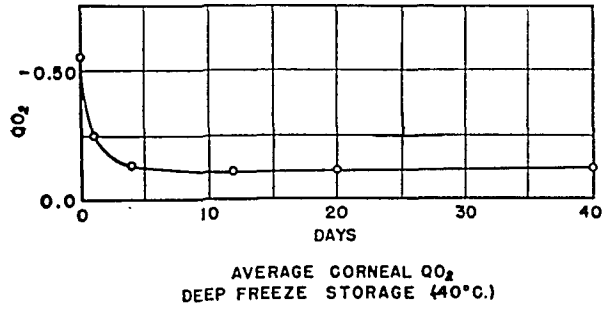

Fig. 4 (Duane). Average corneal QO_2 of isolated corneas stored in the deep freeze at —40°C.

Clinical experience has demonstrated that the storage of donor corneas at low nonfreezing temperatures is only satisfactory for periods of 48 to 72 hours. Longer storage periods almost invariably result in opaque transplants. However, the QO_2 of these corneas remains normal for a considerably longer time than 72 hours.

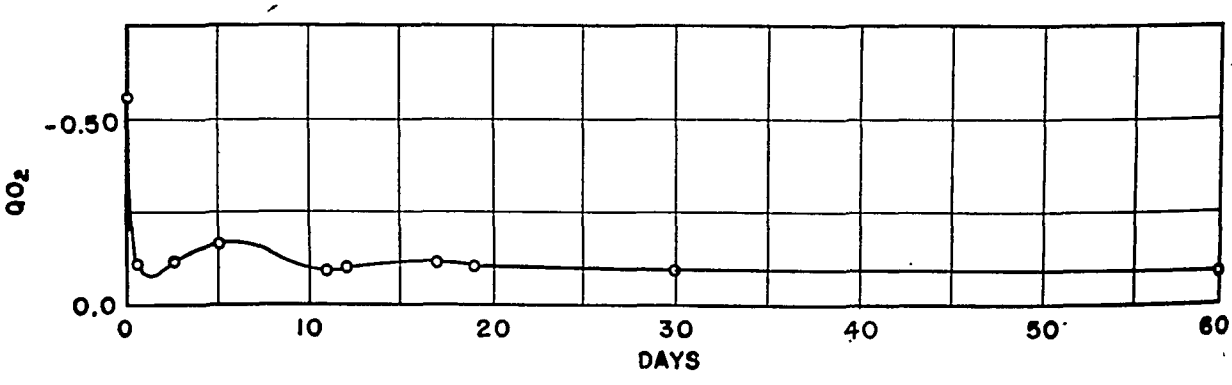

Fig. 5 (Duane). Average corneal QO_2 of isolated corneas stored at —40°C. after quick freezing.

it remained. The absence of bacterial contamination permitted study over a much longer period. At 40 days the QO_2 was still one-fifth normal.

5. At —40°C. after quick freeze. The results obtained on 40 eyes which were included in this group are plotted in Figure 5. Quick freezing reduced the respiration to one-fifth normal and at 60 days it was still at this level.

Discussion

Most mammalian tissues studied with the Barcroft-Warburg technique demonstrate a respiratory rate many times greater than

It was hoped that these experiments might explain the unsatisfactory surgical results on the basis of a change in the activities of respiratory enzyme systems. There appears to be little correlation between the maintenance of a normal QO_2 by a cornea and its suitability for corneal transplantation. However, one should be cautious in transferring the results from bovine corneas to the conditions which exist in human eyes. Furthermore, the present studies do not include measurements of glycolytic activities which may be important for the survival of tissues.

There are certain reports in the literature

that corneas treated with formalin are suitable as donor material for corneal transplants.[5,7] There are many reasons to question these reports[13,14] and the results of the studies reported in this paper cast further doubt on the use of formalin as a storage medium.

The literature on cold death of tissues is well summarized by Heilbrunn,[15] but the actual effect of low temperatures on respiratory enzyme systems is unknown. It is hoped that further investigations may provide answers to some of these questions.

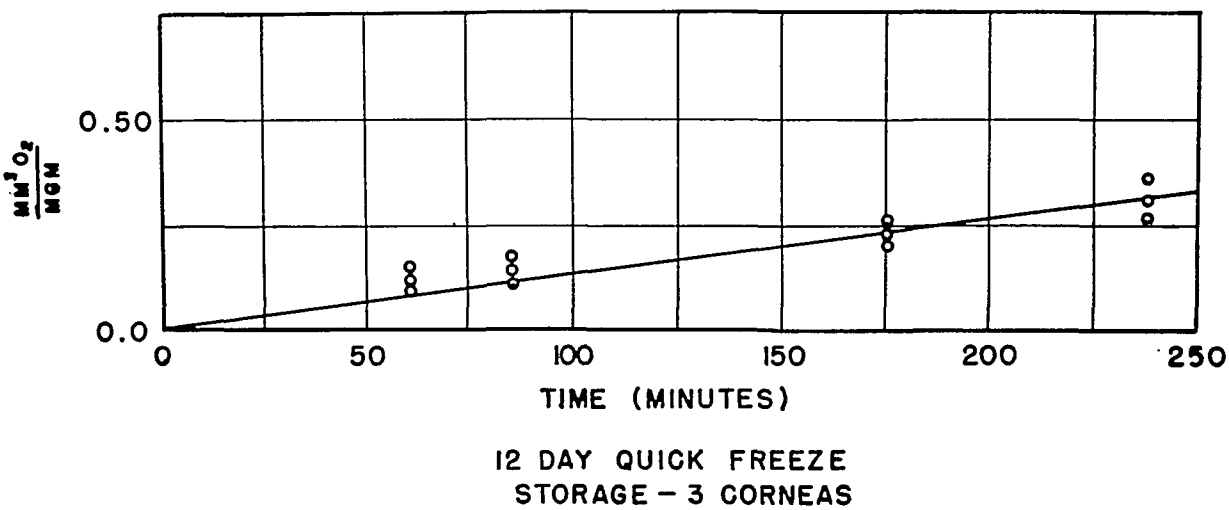

Fig. 6 (Duane). Respiration of three corneas stored for 12 days at —40°C. after quick freezing.

Summary and Conclusions

1. Respiration studies have been made on bovine corneas stored from 1½ hours to 60 days under five different conditions: (1) intact eyes stored above Ringer's solution at 4°C., (2) under oil at 15°C., (3) isolated corneas stored in 5-percent and 35-percent formalin, (4) in the deep freeze at —40°C., and (5) in the deep freeze after quick freezing.

2. The QO_2 of the cornea remains normal when stored over Ringer's solution or under oil at low nonfreezing temperatures for 7 days. The respiratory rate falls to one-fifth normal in 10 to 12 days under these conditions.

3. Formalin inhibits respiration of the cornea immediately and this is apparently irreversible.

4. The corneal QO_2 is reduced immediately to one-fifth normal by quick freezing and drops to this level within 4 days when kept at —40°C. There is no further respiratory depression up to 60 days storage.

SOME FACTORS IN THE SURGICAL TREATMENT OF VERTICAL DEVIATIONS*

JOHN H. DUNNINGTON, M.D.
New York

The uncertainty of postoperative results has deterred many ophthalmologists from attempting the surgical correction of vertical deviations. It is true that such muscle surgery has its disappointments and that there is still much to learn about it, but by taking full advantage of certain known facts, the number of failures can be reduced and more uniform results obtained.

For example, knowledge that most vertical deviations are noncomitant was the first step toward the solution of this problem. Then we began to appreciate the importance of preoperative information on the behavior of the eyes in the six cardinal directions of gaze. The value of accurate measurement of the amount of deviation in the different fields was drilled into us by Duane,[1] White,[2] and others who also showed us that the screen and parallax test was the test par excellence for obtaining such information.

We became increasingly aware of the futility of the old teaching of "tenotomy of the superior rectus is the operation of choice in hyperphoria," for we began to diagnose vertical deviations not as hyperphorias, but as paralyses with or without secondary overactions. The proper surgical treatment is therefore based not only upon the correct preoperative diagnosis of the muscle or muscles involved, but also upon which eye is used for fixation in the different directions of gaze. Failure to consider the presence or absence of a shifting fixation in the preoperative study has done much to increase the variability of the surgical results.

Since most operations upon the vertically acting muscles are designed to give a functional result, they must be more exact. The preoperative studies to be complete should include information on the eye used for fixation in the primary position and in the various directions of gaze. Accepting the general principle that most vertical deviations are of paralytic nature, we can now

* From the Institute of Ophthalmology, Presbyterian Hospital, and the Department of Ophthalmology, College of Physicians and Surgeons, Columbia University, New York City. Read at the III Pan-American Congress of Ophthalmology, Havana, Cuba, January 7, 1948.

consider the exact procedures available for use in specific paralyses* and show the importance of the fixing eye in determining which operation should be selected.

Paralysis of the superior rectus

The frequency of involvement of this muscle has long been a controversial subject. Duane,[3] White,[4] and others have considered a weakness of the superior rectus to be the most frequent congenital ocular muscle anomaly, and list it high as a cause of ocular torticollis; while Bielschowsky,[5] Adler,[6] and others believe that it is much more frequently due to involvement of one of the oblique muscles. Be that as it may, when the diagnosis of paralysis of the superior rectus is made, the following operative possibilities have to be considered.

Operative choices	Indications
1. Strengthening affected muscle	a. Genuine paresis of superior rectus b. Secondary overaction of inferior rectus of same eye c. Fixation with sound eye
2. Weakening of inferior oblique of opposite eye	a. Slight paresis of superior rectus b. Fixation with paretic eye
3. Weakening of inferior rectus of same eye	a. Secondary procedure b. Fixation with the sound eye.

1. Strengthening of affected muscle

To my mind surgery of this type should be employed when these conditions prevail: (a) Genuine limitation of motility in the field of action of the superior rectus. (b) Secondary overaction of the ipsilateral inferior rectus. (c) Fixation is maintained with the sound eye.

The reasons for selecting a strengthening procedure under these conditions are: (a) To improve the elevating power of the paretic muscle. (b) A shortening of the superior rectus mechanically limits the action of the opposing inferior rectus, hence if the inferior rectus is not spastic, serious interference with the downward movement of the eye may follow. (c) When fixation is maintained with the sound eye, no secondary deviation occurs.

Our operative aim, therefore, should be to strengthen the affected muscle rather than to weaken the normal inferior oblique of the opposite eye. It is well to remember that a shortening of the superior rectus is sometimes followed by a slight ptosis which does not always clear up. For this reason, the muscle should not be resected more than about 6 mm.

2. Weakening of the inferior oblique of the opposite eye

Such a weakening can be effected either by myectomy at the origin of the muscle or by a recession at its scleral insertion. Recent studies have shown that recession is the more exact method and in time will probably supplant the older procedure of removing a portion of the muscle near its origin.

This operation is indicated when (a) The limitation of motility of the affected eye is minimal. In these cases, there is no need for increasing the upward motility of the paretic eye. (b) When fixation is maintained by the paretic eye—thus causing a secondary overaction of the contralateral inferior oblique.

For some unexplained reason, in most cases with a slight weakness of the superior rectus, the paretic eye is used for fixation; hence, the widespread belief that a weakening of the inferior oblique of the opposite eye is the operation of choice in all such cases.

Failure to consider which eye is used for fixation accounts for the variable results reported from the use of this procedure. If it is employed when the heretofore mentioned conditions prevail, the results will be remarkably uniform. In rare instances, a

*The term paralysis is loosely used to denote any degree of weakness.

marked paralysis of the superior rectus and secondary spasm of the opposite inferior oblique coexist, requiring the use of both of these procedures.

3. Weakening of the inferior rectus of the same eye

This operation is the procedure of choice when the primary condition is a fibrosis of the inferior rectus which simulates a paralysis of the superior rectus. Such a condition is a common finding in fracture of the floor of the orbit. In these cases, upward motility is impossible because of the adhesions present along the floor of the orbit. Marked improvement in upward rotation follows a recession of the inferior rectus. In all cases of true paralysis of the superior rectus, weakening of the inferior rectus of the same eye is used only as a secondary procedure when the initial strengthening of the paretic muscle has failed to inhibit to a sufficient degree the overactivity of the spastic inferior rectus.

Paralysis of the inferior rectus

A similar analysis of these cases shows the operative choices to be:

Operative choices	Indications
1. Strengthening affected muscle	a. Genuine paresis of inferior rectus b. Fixation with sound eye
2. Weakening of superior oblique of opposite eye	a. Slight paresis of inferior rectus b. Fixation with paretic eye

1. Strengthening of affected muscle

This type of surgery is indicated in those cases showing (a) Genuine limitation of motility in the field of action of the inferior rectus. (b) Fixation with the sound eye. Such an operation may be followed by a slight overcorrection in upward gaze. It is well, therefore, to proceed cautiously unless the deviation is pronounced above as well as below the horizontal plane.

2. Weakening of the superior oblique of the opposite eye

The superior oblique has long been regarded as "noli me tangere;" yet, in carefully selected instances, the surgical weakening of this muscle has produced satisfactory results. The methods for weakening this muscle are: (a) Dislocating the pulley and allowing it to recede into the orbit. The technique of this operation as described by Hughes and Bogart[7] consists of making a small skin incision over the trochlea and displacing it with a periosteal elevator. It produces an effect similar to that caused by an external sinusotomy. (b) Tenectomy of the reflected portion of the tendon within its capsule. This operation recently described by Berke[8] is simple in its execution and effective in reducing the action of the superior oblique without causing a complete paralysis.

Sufficient time has not elapsed to allow a final appraisal of these operations, but at present the latter one bids fair to become an established procedure. Weakening of the superior oblique is indicated in those cases of paralysis of the inferior rectus where fixation is maintained by the paretic eye, thereby producing a marked overaction of the contralateral superior oblique. Such a condition usually exists when the paresis is slight and no great limitation of motility exists in the field of the affected inferior rectus, and fixation is maintained with the paretic eye.

Paralysis of the superior oblique

This muscle is frequently involved and many of these cases require surgery for relief from distressing diplopia. The operative measures to be considered are:

Operative choices	Indications
1. Strengthening affected muscle	a. Genuine paresis of superior oblique b. Marked torsion of image c. Fixation with scund eye

2. Weakening of inferior rectus of opposite eye	a. Slight paresis of superior oblique b. Fixation with paretic eye
3. Weakening of inferior oblique of same eye	a. Secondary spasm of this muscle

1. STRENGTHENING OF AFFECTED MUSCLE

Using the same diagnostic criteria this is the method of choice when there is (a) Genuine limitation of motility in the field of action of the superior oblique. (b) Fixation with the sound eye. Such a strengthening operation is an elaborate surgical procedure first described by Wheeler,[9] in 1934, and more recently modified by McGuire[10] and others. It involves reflecting the superior rectus and either shortening or advancing the superior oblique. Although its usefulness is limited, in cases of paralysis of the superior oblique with marked torsional disturbance, it does much to rid the patient of the annoying tilting of the object.

2. WEAKENING OF THE INFERIOR RECTUS OF THE OPPOSITE EYE

Paralyses of the superior oblique such as result from radical sinus surgery are rarely complete, yet they are sufficient to cause most distressing symptoms. In such instances where (a) The limitation of motility is slight and (b) fixation is maintained with the paretic eye, a recession of the inferior rectus of the opposite eye often produces a most gratifying result.

Such an operation must be guarded to avoid overcorrection. Rarely is it advisable to do more than 2 to 3 mm. Another distressing complication that follows too generous a recession of the inferior rectus is a dropping down of the lower lid with the resultant exposure of bulbar conjunctiva between the lower limbus and lid margin.

3. WEAKENING OF THE INFERIOR OBLIQUE OF THE SAME EYE

This is the operation of choice when the inferior oblique of the same eye manifests a definite overaction which is not an uncommon finding in long-standing cases of paresis of the superior oblique. The spasmodic upshoot can be satisfactorily corrected by a recession of this muscle, but it will have little or no effect on the deviation in the lower field. Its use is therefore recommended only in those cases with secondary spasm of the inferior oblique.

PARALYSIS OF THE INFERIOR OBLIQUE

Isolated paralysis of this muscle occurs not too infrequently as a congenital anomaly. It is most often a unilateral affair, but in rare instances both eyes are similarly affected. They rarely cause discomfort and, in my judgment, are usually best left alone. If one contemplates surgery, the following possibilities have to be considered.

OPERATIVE CHOICES	INDICATIONS
1. Strengthening affected muscle	a. Genuine paresis of inferior oblique b. Fixation with sound eye
2. Weakening of superior rectus of opposite eye	a. Slight paresis of inferior oblique b. Fixation with paretic eye

1. STRENGTHENING OF AFFECTED MUSCLE

This can be accomplished by a tucking or a shortening at or near its scleral insertion, or by advancing the muscle over the orbital margin as described by Wheeler.[9] Neither of these procedures has proven very satisfactory in my hands, but in rare instances when the paralysis is more or less complete and fixation is maintained with the sound eye, one of these surgical measures should be used.

In the cases in which there is a paralysis of both the superior rectus and the inferior oblique of the same eye, fixation is usually maintained with the sound eye. Under these conditions, the proper operative procedure consists of strengthening both of the paretic muscles.

2. Weakening of the superior rectus of the opposite eye

Recession of the contralateral superior rectus is used in those cases where the paralysis is incomplete and fixation is maintained with the paretic eye.

Summary

Recent knowledge has shown that most vertical deviations are of paralytic origin. Selection of the proper operative procedure in a given paralysis depends not only upon the amount of deviation present in the different directions of gaze, but also upon the eye used for fixation. The surgical treatment of each type of paralysis is reviewed, showing the importance of the "fixing eye" in the selection of the proper surgical approach.

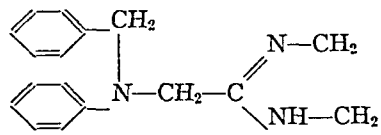
ANTISTINE IN OCULAR ALLERGY*



PAUL HURWITZ, M.D.
Chicago, Illinois

The treatment of the ocular symptoms of itching, lacrimation, photophobia, and secretion in hay fever and allergic conjunctivitis has thus far proved largely unsatisfactory. Little sustained relief for these irritating symptoms is derived from the countless drugs in our medical armamentarium. The drugs include the astringents, vasoconstrictors, soothing agents, local antiseptics, anesthetics, and combinations of several of these medications. More recently the use of vitamins in ointments, locally and orally, has been recommended. All these have been supplemented by the administration of calcium.

Desensitization with pollens and other specific allergens has had less effect on the ocular symptoms than on other symptomatology. Moreover, patients suffering from ocular symptoms alone are reluctant to submit to the prolonged desensitization therapy. Measures directed toward hygienic surroundings and the removal of foci of infections are ineffective in the treatment of allergic episcleritis, phlyctenular keratitis, iritis, uveitis, and endophthalmitis. Air-conditioned surroundings, ocean voyages, trips to seaside resorts and pollen free areas are not available to all, nor is the search for relief always rewarded.

The recent development of the chemical antihistaminic agents shows promise in relieving the symptoms of occular allergy. However, the oral use of benadryl and pyribenzamine has been more effective in relieving the symptoms of allergic bronchitis, rhinitis, and urticaria than the ocular symptoms. The itching, lacrimation, photophobia, blepharospasm, and secretion in many cases of hay fever, allergic conjunctivitis, blepharitis, keratitis, and dermatitis have not been adequately alleviated. To determine the extent of symptomatic relief in the ocular allergies, Antistine, prepared as a solution, was used in a series of cases.

Antistine† is the trade name for a new antihistaminic preparation. The chemical formula is phenyl-benzyl-aminomethylimidazoline. Its structural formula is:

Solutions for ocular topical application contain the sulphate salt in 0.5-percent concentration with a pH of 6.9 in an isotonic buffered solution of the following formula:

Antistine sulphate	18.75 gm.
Sodium carbonate anhydrous	2.66 gm.
Boric acid U.S.P.	46.50 gm.
Potassium chloride	27.75 gm.
Distilled water	3,750.00 cc.

The only previous report of its ophthalmic use is by Bourquin,[1] who reported on it in 37 cases, including conjunctivitis, keratoconjunctivitis, scleritis, iridocyclitis, and ocular trauma. However, there were only a few cases of ocular allergy.

OCULAR ALLERGY

Allergy may affect any portion of the eye or adnexa as has been frequently reported. Bothman,[2] in a comprehensive monograph on ophthalmic manifestations of allergy, cites numerous cases to this effect. Local reactions may attack the lids, conjunctivas, and cornea. General reactions may attack these structures as well as the episclera, sclera, iris, choroid, optic nerve, retina, and

* Presented before the Chicago Ophthalmological Society, February 16, 1948.

extraocular muscles or nerve pathways of the eye.

Allergic reactions of the eye are usually associated with allergic conditions elsewhere in the body, especially with allergic rhinitis and gastrointestinal disorders. Many of my patients had an allergic rhinitis and several were taking atropine by mouth for "spastic" intestinal disorders. A familial history of allergy is common.

Common causes

The most common causes of ocular allergy are found in the categories of inhalants, ingestants, and contactants. Among the inhalants, frequent offenders are the pollens of trees, weeds, and grasses; animal danders, house dust; the seed of cotton, flax, and kapok; and the molds of alternaria and penicillium.

Heading the food list (ingestants) are the cereals, egg, milk, nuts, fish, chocolate, meats, fruits, vegetables, and spices. Among the contactants are poison ivy, silkworm, wool, perfumes, cosmetics, lacquers, orris root, and various drugs applied locally.

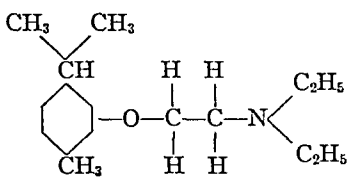
Allergic reaction

The allergic reaction is characterized by a spasm of smooth muscle (in the eye: the iris, ciliary body, arteries, and arterioles), capillary dilatation, and increased permeability. Capillary permeability results in tissue edema with serum and fibrin, leukostasis, and erythrostasis.

Duggan,[3] citing Ricker, explains this reaction as follows: Various stimuli cause constriction of all terminal vascular elements (arterioles). The capillaries become fatigued and relax. There is a subsequent slowing of the blood stream in the capillary bed and a resultant terminal anoxemia. The lack of oxygen causes an increased permeability of the capillary walls. The perivascular exudate presumably contains irritating and toxic H products (histamine) or the end results of antigen-antibody reaction. Duggan aptly states that the "pathologic changes of allergy are due to vascular reactions which are physiologic in nature but pathologic in degree."

Immunologic explanation

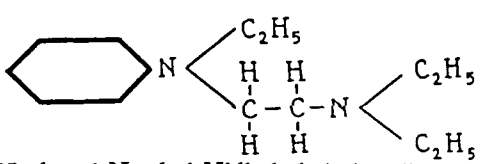
The accepted immunologic explanation of allergy assumes that allergic symptoms do not occur in individuals inherently capable of developing allergic manifestations on first contact with the allergen. This is explained on the basis that normal cells contain no antibody (reagin). Antibody production is stimulated by the initial contact. After a suitable contact and incubation period, reagin will be present in the cells. Upon second exposure to the antigen, the antigen combines with the reagin in the cells and H substances or histamine are released. This is in effect anaphylaxis. In individuals being treated with desensitization, a new antibody is formed which neutralizes the antigen and prevents the antigen from reaching the reagin in the cells. This prevents the production of H substances. No allergic reaction occurs if there is sufficient neutralizing antibody to inactivate all of the antigen.



Antihistaminic agents are presumed to be effective through neutralization of the H substance or through replacement of the space in the cell that might be occupied by histamine. There is experimental evidence to support this contention. Parenthetically, it may be mentioned that the action of the sympathomimetic drugs, epinephrine, ephedrine, and propadrine hydrochloride, do not have a specific immunologic or chemical action in the allergies. They exert their antiallergic action on the basis of their vasoconstrictor properties. In structure all antihistaminics are basically alike in that they contain the ethylenediamine group. The attached number and structure of radicals differ.

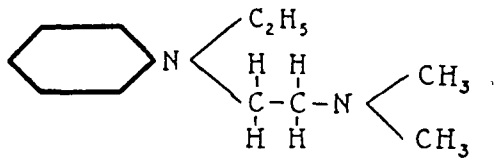
Chemical antihistaminic agents

The development of the chemical antihistaminic agents has been summarized by



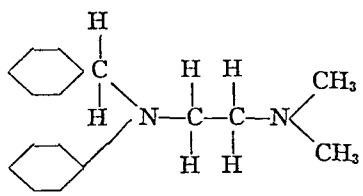
Feinberg.[4] However, since there is little disquisition of the antihistaminic agents in ophthalmic literature, it may be well to devote some space to their history. The awareness of the association of the anaphylaxis and allergic reactions, and the recognition of histamine as an important factor in both conditions, stimulated scientific effort toward neutralizing and rendering ineffective the H factor. In 1933, certain phenolic ethers were found to be effective in counteracting the action of histamine and its anaphylactic properties. Subsequent efforts to discover more effective and less toxic agents resulted in a series of drugs.

The evolvement of the antihistaminic drugs commenced with Fourneau's[5] study of one of the phenolic ethers. This was found to be antianaphylactic and antihistaminic in vivo and in vitro. It is protective against two lethal doses of histamine in the guinea pig, is locally anesthetic, but too toxic. The formula is:



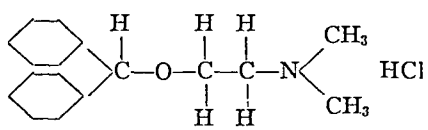
2-isopropyl-5-methylphenoxyethyldiethylamine (Fourneau).

Another chemical agent, in which the ethylenediamine radical was substituted, was explored by Staub[6] and found to be antianaphylactic, protecting the guinea pig against 2 to 6 lethal doses of histamine. It is also antihistaminic but likewise too toxic. The formula is:



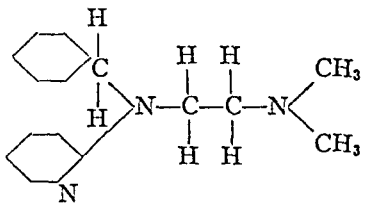
N-phenyl-N-ethyl-N'diethylethylenediamine.

Halpern[7] substituted the dimethyl for the diethyl group. This resulted in a drug of higher antianaphylactic action, protective against 8 to 10 lethal doses of histamine administered to the guinea pig. The chemical formula is:



N'phenyl-N'ethyl-N-dimethylethylenediamine.

Antergan was also studied by Halpern. This compound is formed by substituting a benzyl-group for the ethyl group. This chemical agent, in addition to being antianaphylactic and antihistaminic, is also antiallergic, less toxic than the other products and affords protection against 40 lethal doses of histamine. The structural formula is:



N'phenyl-N'benzyl-N-dimethylethylenediamine.

Benadryl hydrochloride made its appearance in this country as an antiallergic agent. It is effective in urticaria, dermatitis, and asthma. Frequent side reactions are dizziness and drowsiness. The structural formula is:

Beta-dimethylaminoethyl benzohydryl ether hydrochloride.

Pyribenzamine differs from antergan in the substitution of the pyridil for the phenyl ring. It is antiallergic, effective in urticarial dermatoses, hay fever and vasomotor rhinitis, and asthma. The side reactions are not serious and consist primarily of drowsiness and lassitude. The structural formula is:

N'pyridil-N'benzyl-N-dimethylethylenediamine.

Pharmacologically, it has been determined[8] that Antistine has a very low toxicity, does not accumulate rapidly, and has strong antihistaminic activity. This latter activity has been demonstrated by its ability to negate the stimulating effect of histamine phosphate on the isolated ileac strip of the guinea pig.

Antistine also prevents bronchial spasm, produced by histamine in the isolated perfused lung of the guinea pig and in the living animal, and it decreases appreciably the hypotensive action of histamine in dogs. This holds true in local as well as general application. Antistine does not inhibit antibody production. The protection afforded by the antihistaminic property of Antistine permits a greater antibody production by allowing the animal to tolerate a larger amount of the injectable antigen.

Clinically, Schindler[9] found Antistine, used orally, subcutaneously, and intravenously, an effective antiallergic agent in 39 patients. This group included bronchial asthma, urticaria, pruritis, and erythema nodosum.

Brach[10] reports that Antistine counteracts the itching of urticaria, eczema, neurodermatitis, prurigo, lichen ruber planus, psoriasis, and nervous pruritus. In urticaria the skin changes are counteracted or prevented. Brach states, too, "Antistine seems to suppress the itching regardless of whether it is elicited by sympathicotonic or parasympathicotonic factors, which seems to indicate that the itching is always produced by H substances."

Antistine also achieves some effect through its peripheral influences on the vasomotor action that evokes the itching. Liberated histamine thus is prevented from exerting its effect. In addition to this action there is a slight local anesthetic action. Antistine orally is well tolerated. No serious side effects have been observed. Occasional complaints are nausea, epigastric distress, vertigo, palpitation, flushing, and drowsiness.

Case reports

Presented are 50 cases of ocular allergy. For the purposes of this study, the cases are divided into the following groups:

1. Hay fever with simple allergic conjunctivitis.
2. Hay fever complicated by other allergens and by pathologic conditions other than conjunctivitis.
3. Allergic conditions other than hay fever.
4. Vernal catarrhal conjunctivitis.
5. Palpebral urticaria, dermatitis (eczematoid and atopic), and angioneurotic edema.

No effort is made to justify this classification, except that the cases seem to be best suited to this division. In none of the cases were blood studies or conjunctival smears for eosinophilia made. In each case there was adequate clinical evidence to warrant the diagnosis. In most instances, skin tests were made. Cases which did not meet standard criteria to establish the diagnosis of ocular allergy were not included in this series.

Group 1. Hay fever with allergic conjunctivitis

In this group are 15 cases of typically characteristic hay fever with allergic palpebral conjunctivitis. The ragweed pollen was the dominant factor in the production of the symptoms. Although skin tests in many of these cases revealed hypersensitivity to other antigens, this hypersensitivity was subclinical.

Mrs. N. H. had complained for 5 years of seasonal sneezing, coughing, nasal discharge with

ocular itching, tearing, and redness. These symptoms coincided with the hay-fever season and were unusually severe this past year. There were present a typical allergic conjunctivitis with edematous palpebral conjunctivas and an allergic rhinitis with pale and boggy nasal mucosa. Skin tests were strongly positive to ragweed, cockle burr, wormwood, and many foods. Previous local treatment with many ophthalmic preparations were without value. Benadryl and pyribenzamine, orally, relieved mildly the sneezing and coughing but did not alleviate the ocular symptoms. One drop of Antistine ophthalmic solution completely relieved the ocular itching and tearing for periods of 4 to 6 hours. Three drops in each eye daily gave total relief from all ocular symptoms. The Antistine solution was used for a period of 6 weeks with constant relief. A momentary smarting sensation followed the instillation of the solution.

Fourteen additional cases of typical hay fever with allergic conjunctivitis are presented. For the sake of brevity, comment is made solely on differing aspects of symptomatology or response to treatment.

Mrs. E. E. had typical hay fever and allergic conjunctivitis and was taking atropine orally for a "spastic colon." She complained of blurring of vision and itching of both eyes. She was hypersensitive to ragweed. One drop of Antistine solution, instilled locally twice daily, completely relieved the itching and the blurring of vision.

C. G., aged 10 years, had hay fever with follicular conjunctivitis, itching, and secretion of both eyes. Complete relief from the itching and secretion was obtained with one drop of Antistine ophthalmic solution instilled every morning. The size of the conjunctival follicles was visibly reduced following the instillation of the solution. Constant ocular rubbing was obviated.

Mrs. E. C., with typical hay fever of many years' duration, complained of blurring of vision, ocular itching, nasal stuffiness, and a tickling sensation of the throat. One drop of Antistine solution daily completely eliminated the blurring and itching.

Mrs. E. H. had typical hay fever. She complained of a distressing ocular heaviness, epiphora, and itching. Adrenalin, neosynephrine, and boric-acid irrigations gave no relief. One drop of Antistine solution completely relieved all symptoms for 6-hour periods for the first 3 days. After the third day, only one drop a day was necessary to give total symptomatic relief.

J. C., aged 9 years, had hay fever with allergic conjunctivitis, rhinitis, and bronchitis. He suffered sneezing and wheezing and complained of ocular itching, secretion, a burning sensation, and the intense desire to rub his eyes. One drop of Antistine solution instilled in both eyes, morning and night, gave complete relief from all ocular symptoms. After the first week, one drop each night relieved all symptoms and the patient no longer rubbed his eyes (to the mother's great relief). The side reaction to the Antistine consisted of a momentary burning and a "watery sensation."

C. R., aged 8 years, had typical hay fever with sneezing and ocular irritability. She could not tolerate Antistine solution because of the intense smarting sensation following instillation.

Miss P. H. had typical hay fever with rhinitis and conjunctivitis each summer for several years. The palpebral conjunctivas were hyperemic and thickened. She obtained complete relief from ocular itching and epiphora by using one drop of Antistine solution, daily, in both eyes for two days and then one drop every second day. After one week the solution was stopped. For 12 days she was symptom free. She then used one drop in each eye for several days, and discontinued the solution 3 weeks before the termination of the hay-fever season. She continued asymptomatic for the remainder of the pollen season, despite a high pollen count.

Mrs. T. F. had typical hay fever with severe itching and tearing for many summers. (Her son had a vernal conjunctivitis.) Her symptoms were completely relieved by one drop of Antistine solution 3 times a day. Neosynephrin and estevin were prescribed as control measures during the hay-fever season. She stated that these drugs did not compare favorably with Antistine in the degree of relief obtained. She experienced severe momentary burning upon instilling Antistine.

Mrs. M. S. is a typical hay-fever patient with distressing ocular lacrimation and photophobia. She had subjected herself to every known therapy, including the antihistaminics orally, but without relief. Even air-conditioned surroundings gave only mild comfort. Antistine ophthalmic solution gave immediate and prolonged relief from the lacrimation, photophobia, and itching and even relieved her rhinorrhea and sneezing.

Mrs. E. B. developed hay fever with typical ocular symptoms during the course of an attack of endophthalmitis and keratitis, which complicated a cataract extraction performed elsewhere. Treatment with atropine produced an atropine dermatitis. Antistine solution relieved the symptoms of the eczematoid dermatitis. One drop a day, for 6 days, controlled the ocular symptoms of the hay fever and, thereafter, treatment was not necessary. This improvement occurred before the end of the hay-fever season. Surprisingly, intensive antihistaminic therapy resulted in an accelerated improvement in the endophthalmitis. It is likely that the pathologic conditions in this case may have had an allergic basis.

Mrs. E. H. had characteristic hay fever with rhinitis and conjunctivitis. She complained of itching and tearing of both eyes. She was sensitive to ragweed, silk, and wool. One drop of Antistine solution, 3 times daily, relieved completely the symptoms. An unexplained skin lesion of both cubital spaces disappeared after the institution of an antiallergenic regimen.

Mr. G. C. had typical hay fever with ocular

itching and tearing. Skin tests were positive to ragweed. On September 15th he was given Antistine solution. He used two drops, 3 times daily, in both eyes for 3 days. At this time, prior to the end of the hay-fever season, he became symptom free and discontinued the use of the Antistine solution.

M. I., aged 10 years, had hay fever with ocular tearing for several years. Desensitization was without effect. The tearing ceased with the use of Antistine solution.

H. S., aged 6 years, had seasonal allergic conjunctivitis with itching, redness, and secretion of both eyes. (The patient's mother was allergic to foods and pollens.) Antistine solution completely eliminated the symptoms.

Comment

Several observations can be made from this group of cases. All patients, except one, obtained immediate and dramatic relief from all ocular symptoms with the use of Antistine ophthalmic solution. The amount of solution necessary to allay the itching, tearing, and lacrimation varied from one drop 3 times a day to one drop every second day. Several patients experienced extended periods in which ocular therapy was unnecessary. Other patients were able to discontinue the Antistine solution prior to the termination of the hay-fever season. This indicates a cumulative therapeutic effect of the action of the antihistaminic agent when applied locally. It is apparent that the antihistaminic agent successfully combats the histamine for space in the cell when applied locally, as well as systemically.

In most instances the local application of Antistine ophthalmic solution causes temporary smarting of varying degree. No other significant side reactions were noted in this series.

In two instances, where blurring of vision was present (one case where the patient was taking atropine by mouth), the use of Antistine solution relieved the blurring.

In most patients, Antistine did not alter the pathologic status of the conjunctivas, except to contract the superficial vessels slightly. In one case of follicular conjunctivitis, the size of the follicles was noticeably reduced following instillation of Antistine.

A comparison of the value of Antistine ophthalmic solution with other ocular medications in relieving the ocular symptoms of hay fever, was greatly in favor of Antistine. This pertains to degree and duration of relief. Use of the solution also proved superior to air-conditioned surroundings.

Group 2. Hay fever associated with other allergens and pathologic conditions

In this group are cases in which the ragweed pollen was a major, but not the sole, antigenic factor. Other ocular pathologic conditions besides allergic conjunctivitis existed.

H. G., aged 13 years, complained of ocular itching, photophobia, redness, and intense blepharospasm. The symptoms were perennially present but were exaggerated during August and September. The palpebral conjunctivas were injected, boggy, and hypertrophic. Skin tests revealed a hypersensitivity to ragweed, molds, dust, and many foods. Previous treatment, consisting of desensitization, and of adrenalin, neosynephrin, estevin, and many collyria locally, failed to give even moderate symptomatic relief. During the summer months, photophobia and blepharospasm were intense in the presence of sunlight. Antistine ophthalmic solution, instilled locally 4 to 5 times a day, gave complete ocular relief. After prolonged use of the Antistine, the palpebral conjunctivas assumed a normal appearance.

Mrs. D. R. complained of itching, burning, and photophobia all year round. She was hypersensitive to the glare of snow and sun. During the hay-fever season there was a typical allergic conjunctivitis. One drop of Antistine solution, every second day, relieved all symptoms.

Mrs. E. B. had hay fever, perennial conjunctivitis, rhinitis with sneezing, and itching, burning, and redness of both eyes. In addition, she had frequent recurrent hordeola. One drop of Antistine, daily, relieved all symptoms. Oral antihistaminics had no effect on the ocular symptoms. The occurrence of bacterial infection and hordeola on a fertile allergic soil is noted. For the past 6 months, with the use of the solution, there have been no styes nor injection of the lid margins.

A. C., aged 20 years, has had typical hay fever for the past two summers. He complained of severe itching, redness, and discomfort of both eyes. The palpebral conjunctivas of both eyes were injected, succulent, and presented the characteristic

picture of an acute catarrhal conjunctivitis. Five-percent sodium sulfathiazole solution was prescribed. Its use for 10 days resulted in an improvement of the conjunctival injection and succulence, but the itching and ocular discomfort did not abate. Antistine ophthalmic solution was then used and the symptoms were immediately mitigated. For the first week, three drops daily were required, but thereafter only one drop per day was necessary to obtain complete symptomatic relief. The palpebral conjunctivas reverted to normal one week after treatment with the Antistine solution was instituted. Skin tests were strongly positive to ragweed, house dust, many foods, and vitamin C. Represented here is an acute conjunctivitis superimposed upon an allergic base. The use of Antistine solution prior to the sulfathiazole solution was not effective. A combination of the two might have proved successful.

Miss C. W. suffered from typical hay fever with ocular itching for several years. Prior to the onset of the hay-fever season, she had two attacks of acute iritis, and was seen by me during the second. In addition to other therapy, 30-percent sodium sulfacetimide solution, locally, was prescribed. This resulted in an allergic palpebral dermatitis and conjunctivitis. The patient was treated with Antistine ophthalmic solution and Antistine tablets (400 mg.) daily. The iritis, dermatitis, and conjunctivitis rapidly improved. Thereafter, during the hay-fever season, one drop of Antistine ophthalmic solution, every 2 or 3 days, controlled the ocular itching. The boggy conjunctivas became normal in appearance. Skin tests were positive to grasses, molds, trees, house dust, sulfathiazole, and many foods. In this case, the allergic etiology of the iritis was unsuspected until the reaction to the sulfacetimide developed. The prompt response to antihistaminics was further verification of the allergic etiology.

D. D., aged 9 years, with a familial history of allergy, suffered from perennial itching, epiphora, and recurrent redness of the eyes. During the hay-fever season, the condition was aggravated. Previous therapy, with zinc, adrenalin, boric acid, estevin, and various ophthalmic ointments, resulted in only mild relief. When the patient was seen in the spring of the year, there were present characteristic boggy palpebral conjunctivas, a limbal injection, and punctate areas of corneal tumefaction in each eye. Antistine ophthalmic solution, instilled 3 to 4 times a day, relieved all ocular symptoms. The pathologic conditions subsided during the hay-fever season, while on Antistine solution treatment, and the ocular symptoms were so mild that medication was felt unnecessary for periods of weeks. This is a case of typical hay fever with perennial allergic manifestations of limbic keratoconjunctivitis.

Miss M. Z. suffered with recurrent corneal ulcerations for 13 years. For the first 10 years, these occurred only in the summer, but more recently have occurred several times a year. The duration of the attacks varied from a few weeks to several months. Severe photophobia, blepharospasm, lacrimation, and redness of the eyes were present. There was a hypersensitivity to many antigens including pollens and dust. With the slitlamp, numerous diffuse areas of corneal infiltration, ulceration, and extensive superficial vascularity were noted. Every known therapy was applied without appreciable effect. Antistine tablets (400 mg. daily) orally, and Antistine solution, 3 times daily in both eyes, were administered. After therapy for one week, the patient stated she had experienced "100-percent relief." Antistine solution markedly decreased the corneal vascularity.

B. H., aged 15 years, complained of ocular itching throughout the year. Skin tests revealed hypersensitivity to ragweed, wool dust, and tree pollens. One drop of Antistine solution every morning in both eyes gave complete relief from the itching.

Comment

In this group are cases of hay fever, associated with other allergens and pathologic conditions besides allergic conjunctivitis. Included are bacterial complications. Presented are cases of allergic iritis, limbic keratoconjunctivitis, infiltrative and ulcerative keratitis, and allergic conditions, complicated by acute catarrhal conjunctivitis and recurrent hordeola. The two patients, who had intense hypersensitivity to the glare of sun and snow, disproportionate to the pathologic conditions present, may be considered cases of physical allergy. All patients in this group showed a remarkable response to Antistine ophthalmic solution.

Group 3. Ocular allergy without hay fever

Mr. N. Z. was undergoing desensitization treatment for a perennial allergic asthma at a Veterans hospital. He complained of constant ocular itching and redness of the lids for 4 years. Skin tests revealed a hypersensitivity to a number of foods including beef, tea, spinach, and apples. Characteristic allergic palpebral conjunctivitis was present with a superimposed subacute catarrhal conjunctivitis. One drop of Antistine ophthalmic solution daily gave complete relief from ocular itching and the redness of the lids subsided. The palpebral conjunctivas assumed a normal appearance. Previous treatment with other medication had been unsuccessful.

R. G., aged 14 years, complained of recurrent itching and tearing of both eyes for two years.

There was a typical mild allergic conjunctivitis. Skin tests were positive to many foods, kapock, and feathers. Antistine ophthalmic solution, used twice a day, completely relieved the itching and tearing. Other medication, previously used, was to no avail.

Mr. N. M., aged 29 years, complained of a marked redness of the lid margins and ocular discomfort for many years. He gave a history of recurrent attacks of hives and sneezing. Of numerous local medications used, neosynephrin, ⅛-percent solution, and penicillin solution gave some relief. Skin tests were positive to many foods, including fish and coffee, and strongly positive to house dust. Antistine ophthalmic solution, 3 times daily, completely relieved the ocular discomfort and decreased the hyperemia of the lid margins. The patient stated that his eyes "felt fine." However, a moderate redness of the lid margins persisted even after prolonged treatment. In this case it is felt that the therapeutic response was not complete because of the hypersensitivity to dust. On a trip to New Orleans he partook of fish and coffee and developed a marked palpebral urticaria, which promptly responsed to Antistine, locally and orally.

Mrs. R. S. complained of itching and pain in both eyes. There was a mild hyperemia of the palpebral conjunctivas. Skin tests revealed a marked sensitivity to wool products. Antistine ophthalmic solution was prescribed. The patient instilled only one drop in one eye and experienced a hollow sensation in the eye and a sinking sensation in the epigastrium. This case is presented as an unusual side reaction to the Antistine solution, possibly on a basis of vagus stimulation. The patient dreaded the use of the solution and would not permit its repetition.

Mrs. F. K. had recurrent attacks of ulcerative blepharoconjunctivitis for many years. She also had recurrent attacks of hives, rhinitis, and periodic swelling, scaling, and itching of the skin of the upper lids. There was present a typical allergic conjunctivitis. When first seen the patient was using sulfathiazole ointment for the ulcerative marginal blepharitis and the condition was increasingly worse. Penicillin ointment likewise aggravated the situation. Skin tests were positive to wool products, many foods, fingernail polish (lacquer), and cat hair. Antistine ophthalmic solution was prescribed and used for one week with no apparent improvement. Penicillin, in solution, was then prescribed for use with the Antistine solution. After 10 days of combined treatment, the blepharoconjunctivitis improved. With the continued use of Antistine, the patient has been asymptomatic for many months. Illustrated, in this case, are the association of an infectious condition with allergy; the negative response to antibiotics in lanolin ointments, in patients hypersensitive to wool products; and the efficacy of the combined treatment with antibiotics and antihistaminics.

Mr. P. F., aged 39 years, for the past 3 years was subject to frequent attacks of hordeola and ulcerative blepharoconjunctivitis. He complained of itching, burning, and redness of both eyes. Many ocular medicaments, including the antibiotics, gave only mild and temporary relief. Skin tests were positive to molds, wool, grass, pollens, ragweed, many foods, and feathers. Antistine ophthalmic solution, used twice daily, relieved all ocular symptoms. After using Antistine for 2 weeks, the patient felt so improved that he was ready to forego further treatment. For 6 months, while on an allergic regimen and Antistine solution, he had only one hordeolum. This was by far the longest period in 3 years in which he was free of symptoms. (Since this was originally written the patient went to Florida, broke his diet, lost his medicine, and developed a marked blepharoconjunctivitis.)

Mr. T. G., aged 44 years, had a bilateral blepharitis squamosa with conjunctivitis. This has been present for many years. He complained of bilateral redness of the lid margins, a burning sensation, and photophobia. Skin tests were positive to yeast, coffee, garlic, onions, and markedly so to house dust. Desensitization with house dust was without benefit. Antistine solution, used 3 times a day for 3 months, gave no relief from the symptoms, although the hyperemia of the lid margins decreased somewhat. Illustrated again is the failure of Antistine solution to relieve the symptoms in the presence of a marked hypersensitivity to house dust.

Mr. N. B. had recurrent attacks of blepharoconjunctivitis and palpebral dermatitis for several years. The palpebral conjunctivas were injected and granular in appearance. Previous medication used was ineffective. Skin tests revealed hypersensitivity to ragweed, Russian thistle, alfalfa, horse hair, novocaine, and mercurials. The use of Antistine ophthalmic solution resulted in great improvement, subjectively and objectively. The granular appearance of the conjunctivas was much decreased.

Mrs. S. M. suffered with recurrent blepharoconjunctivitis. There was hyperemia of the lid margins, edema of both upper lids, and infection of the palpebral conjunctivas. Skin tests were positive to house dust, wool, yeast, many foods, and all the vitamins. Antistine solution caused smarting and tearing of both eyes, puffiness of the lids, and ocular irritability. No improvement was noted.

Mrs. F. N. had recurrent cyst formation of the bulbar conjunctivas for several months. Antistine solution caused a temporary improvement but the condition recurred and Antistine was of no value. Skin tests were positive to dust, lacquer, chlorine, vitamin C, and many foods. Excision of the cysts resulted in a cure.

S. F., aged 10 years, complained of occasional ocular itching and nasal stuffiness for the past two years. Characteristic follicular allergic conjunctivitis and allergic rhinitis were manifest. Skin tests were positive to wool, feathers, chocolate, tobacco smoke, and linseed oil. Antistine ophthalmic solution, periodically used, completely relieved the itching.

COMMENT

In this series of 11 cases, 7 were improved with the use of Antistine solution. The 4 patients in whom no improvement resulted were markedly hypersensitive to house dust.

GROUP 4. VERNAL CATARRHAL CONJUNCTIVITIS

The resistance to all forms of treatment in cases of vernal conjunctivitis is well known. Recent reports on the use of Beta irradiation holds promise of improved treatment. However, for symptomatic relief, the unceasing search is often pathetic. All four patients cited below submitted to every known type of treatment, including surgery, application of dry ice, radium and X-ray exposure, without significant relief.

R. A., aged 13 years, has had typical vernal catarrh for the past four years. There were hypertrophic granulations and the cobble-stone appearance of the upper palpebral conjunctivas. Allergy tests were not made. There were no known allergies, but the patient's father has hay fever. Estevin, adrenalin, and acetic-acid solutions were of no value in relieving the ocular itching, irritability, secretion, or photophobia. Antistine ophthalmic solution, instilled at bedtime, was effective in obtaining symptomatic relief for about four hours, after which the patient awakened because of the ocular irritability. This again was relieved by a drop of the Antistine solution. During the day one drop of the solution, instilled every 3 to 4 hours, has given complete symptomatic relief. The pathologic state remains unchanged.

J. F., aged 12 years, has had vernal conjunctivitis for a number of years. His mother has hay fever. There were exuberant granulations and excrescences of the upper palpebral conjunctivas. The lower palpebral conjunctivas were thickened and pale, and the inferior cul-de-sacs had a cobblestone appearance. There was a thick viscid secretion, also itching, tearing, photophobia, redness of both eyes, and marked ocular discomfort. Skin tests were positive to wheat, rye, corn, oats, vegetables, grasses, pollens, and dust. Antistine ophthalmic solution, instilled 3 times daily, dramatically improved all the symptoms. The secretion was greatly diminished and the itching and tearing were entirely eliminated. The pathologic picture remains unchanged, but for the first time in many years the patient feels comfortable.

R. R., aged 9 years, has had vernal catarrh since early childhood. There were palpebral conjunctival granulomas and excrescences with severe itching, photophobia, blepharospasm, secretion, and a ptosis of the left upper lid due to the weight of the excessive granulation tissue. All therapy, including radium, X-ray exposure, and climatic change, has had no favorable effect. Skin tests were essentially negative to all antigens. Antistine solution, instilled 3 times daily, greatly relieved all symptoms. The mother stated that no medication previously used (including estevin, adrenalin, and neosynephrin) approximated the efficacy of the Antistine solution.

Mr. T. K., aged 34 years, was treated since early childhood for "trachoma" and allergy of the eyes, without improvement. He had a typical vernal catarrh with superior palpebral conjunctival grape-like excrescences, ocular itching, secretion, and swelling of the lids. Marked and lasting relief from all the symptoms, including a "bloated" feeling of the eyes, was obtained by the use of Antistine solution, 3 times daily. For a short time the Antistine solution became irritating and caused a sensation of smarting and ocular dryness, but after a short rest period, the patient was able to resume the Antistine without untoward effects. Skin tests were not made.

COMMENT

This series indicates the marked symptomatic relief obtained by Antistine ophthalmic solution in vernal catarrh. Although the pathologic conditions remained unchanged during the course of many months of treatment, the relief from the distressing symptoms was highly gratifying. Instillations had to be maintained on a basis of 3 to 4 times daily. There was no evidence of a cumulative effect of the therapy. During the long continued course of the therapy, no deleterious effect from Antistine solution was observed.

GROUP 5. PALPEBRAL DERMATITIS, URTICARIA, ECZEMA, AND ANGIONEUROTIC EDEMA

Miss F. M. had an acute attack of swelling, redness, and scaling of the skin of both upper lids with ocular itching, photophobia, and sneezing. Skin tests were positive to ragweed, house dust, many foods, lacquer, tobacco, and vitamins A and D. Several months after her first appearance, the patient developed typical hay fever for the first time. Antistine solution, instilled 3 times daily, immediately and completely relieved the itching and photophobia. Removal from contact allergens resulted in a rapid cure of the palpebral dermatitis.

Mrs. E. B. suffered from recurrent attacks of palpebral dermatitis of both upper lids for 10 years. The present attack was of 3 months' duration. No previous therapy was of value. There were redness

and scaling of the upper lids with itching and burning of both eyes. Skin tests were positive to feathers, foods, pine products, and lacquer. The patient was taking atropine for a "spastic bowel." Antistine solution, locally, relieved the itching and burning sensation of the eyes, but the dermatitis was unaffected. Antistine solution, applied in the form of moist packs to the lids, was similarly not efficacious in altering the dermatitis.

Mrs. S. L. developed a palpebral contact eczematoid dermatitis, following the use of sulfathiazole ointment in the treatment of an obstinate ulcerative marginal blepharitis. With the use of Antistine ophthalmic solution, the contact dermatitis rapidly improved. Surprisingly, the blepharitis also promptly healed. Cessation of the use of Antistine was followed by a recurrence of the blepharitis. The offending allergens were lanolin and a certain type of soap. With the elimination of these agents, the condition improved without recurrence.

Miss H. S. had a typical bilateral allergic palpebral dermatitis. There were redness, thickening, and itching of the skin of both upper lids. Skin tests were positive to lacquer, foods, feathers, dust, and rayon. Antistine solution, instilled as drops, was only mildly effective in allaying the itching. Antistine solution, applied as moist packs, gave no relief. Paradoxically, it caused more itching of the skin. Antistine tablets (300 mgm.) orally, daily, relieved the redness and scaling of the skin of the upper lids. When Antistine tablets were discontinued, the condition recurred.

Mrs. M. K. had a typical acute palpebral angioneurotic edema of both upper and lower lids. She also had an allergic rhinitis and had had migraine headaches in early adult life. She experienced burning, itching, and foreign-body sensation of both eyes. Skin tests were positive to many foods and drugs. One drop of Antistine ophthalmic solution resulted in a marked and visible reduction of the palpebral edema within 20 minutes. The itching and burning were immediately alleviated. Antistine solution was used 4 times daily for 14 days with effective relief from symptoms. However, subsequently, the solution diminished rapidly in efficacy and gave relief for only 10- to 20-minute periods. Oral antihistaminics were ineffective.

Mrs. E. S. complained of continuous severe itching of the skin of the lower lids for many years. No pathologic condition of the skin was evident. Skin tests were positive to timothy, cotton seed, feathers, many foods, pine, and chlorine. Antistine solution was of no value. Antihistaminics orally were also of no value. It is felt that, although the pruritus may have been on an allergic basis, there also existed a strong psychosomatic factor.

Mrs. M. G. had, for the past 5 years, recurrent urticaria of the right upper lid, characterized by redness, scaling, edema, and itching of the skin. Scratch tests were positive to feathers and wool. Oral antihistaminics were of no value. Antistine solution, in moist packs applied to the skin of the lids, decreased the itching and resulted in ocular comfort. A moderate improvement was noted. There were less redness and scaling. Antistine, in a greaseless ointment base, gave more marked and lasting objective improvement.

Mr. P. L. had an eczematoid dermatitis of the left lower lid as a result of being treated with penicillin ointment. Antistine solution, instilled, resulted in immediate relief from the itching sensation and ocular irritability. The dermatitis subsided with unusual rapidity.

Mrs. R. M. had atopic palpebral urticaria of both upper lids for 16 months. She complained of itching, redness, and aching of both eyes. Skin tests were positive to many foods, animal hair, pollens, and molds to a mild degree. Antistine solution, in drops and moist packs to the lids, relieved the itching. The redness and edema of the lids disappeared.

Mrs. G. developed repeated attacks of Quincke's edema during therapy for glaucoma. Each of the four lids was alternately involved. The skin of the lids was tense and slightly pink, with itching. Antistine ointment, in a greaseless base, applied to the skin of the lids, and Antistine solution, instilled in both eyes, relieved the itching and facilitated rapid healing. Skin tests were positive to feathers, lanolin, cottonseed, and foods.

Mrs. E. G. developed a marked urticarial swelling of all four lids, following the ingestion of phenobarbital. There were ocular tearing, itching of both eyes, and swelling of all four lids. A year ago she had an attack of hives. Skin tests were positive to cottonseed, feathers, wheat, pork, lacquer, vitamin E, and orris root. Antistine ophthalmic solution and Antistine ointment, applied to the skin of the lids, resulted in prompt symptomatic and objective improvement of the urticaria. Application of the ointment caused a moderate burning sensation for about 10 to 15 minutes.

Mr. A. F. had bilateral atopic palpebral urticaria with smarting and tearing of both eyes and swelling of the lids. This condition existed continually for many years. Allergy tests were positive to various foods and fruits. Antistine solution gave some relief from the tearing and smarting, but the pathologic status remained unchanged. The value of the Antistine was at best questionable.

Comment

In 9 of the 12 cases presented, there were varying degrees of improvement with Antistine. In most cases the symptomatic improvement was much greater than the objective. Pathologic improvement resulted more readily in the contact dermatitis and the more acute forms of palpebral atopy. The chronic urticarias and dermatoses, although somewhat improved, did not respond in great measure. The action of Antistine in reducing the angioneurotic edema in one

case was dramatic but not enduring. Antistine solution, applied as moist packs, was mildly effective in these cases. Antistine ointment proved more efficient in relieving the itching of the skin and was also found to have some salutory effect on the skin lesions.

TABLE 1

TABULATION OF CASES TREATED WITH ANTISTINE

Group	No. of Cases	Improved	Not Improved
1	15	14	1
2	8	8	0
3	11	7	4
4	4	4	0
5	12	9	3
TOTALS	50	42	8
Percentages	100	84	16

DISCUSSION AND SUMMARY

In 50 cases of ocular allergies, Antistine ophthalmic solution, used locally, proved of definite therapeutic value. Eighty-four percent of the patients showed subjective (symptomatic) improvement. There was moderate to complete relief from itching, photophobia, lacrimation, conjunctival injection, blurring of vision, secretion, and ocular irritability. The most apparent benefit occurred in the patients of Groups 1 and 2, in which the dominant allergen was the ragweed pollen.

The dosage required to maintain symptomatic relief varied from one drop of Antistine solution, every 3 to 4 hours, to one drop daily, and in some cases only one drop every second day. A review of the cases indicates that Antistine solution, locally instilled, has a pronounced antihistaminic effect that is cumulative. It is retained locally in the tissues for a prolonged period of time. Its efficacy is much greater than that of any of the other ophthalmic medications employed in ocular allergy.

In most instances, the instillation of Antistine caused momentary smarting. In several of the described cases, the smarting was more severe, although of short duration, and in one case there was intense burning. Administered in my own eyes, the smarting sensation was fleeting. Despite the side reactions, the patients who derived relief did not feel that the burning was sufficient reason for discontinuing the use of Antistine. Only one patient experienced an untoward reaction; that is, the feeling of a "hollow sensation" in the eye.

Significant is the fact that many of these patients had not previously received ocular symptomatic relief from oral antihistaminics or from any other type of therapy, including desensitization. However, their response to the Antistine solution, locally, was notably good.

A concomitant symptomatic effect was the decrease of visual blurring in two patients who were taking atropine, orally, for "intestinal spasticity." In several cases there was also noted an improvement in the relief from associated rhinorrhea and sneezing.

The relief obtained in cases of photophobia was encouraging. Two patients were intensely sensitive to the glare of sun and snow. These cases were severe enough to merit consideration in a category of ocular physical allergy. Both patients responded favorably to Antistine solution.

The immediate visible effect of Antistine is the contraction of the superficial vessels and blanching of the conjunctivas. In a case of keratitis, with superficial and deep vascularity, it was found that only the superficial corneal vessels contracted. Vascular constriction may be partially responsible for the ocular symptomatic relief and is, no doubt, highly responsible for the diminution of the photophobia. The vascular contraction is prolonged and is not followed by a secondary vasodilatation, such as occurs after the instillation of adrenalin. A slight superficial anesthetic effect is another action of locally instilled Antistine.

Although the pathologic processes were not objectively altered in the majority of the patients treated, and although Antistine solution cannot be considered curative,

nevertheless, many cases responded with a decrease in the edema, hypertrophy, and folliculosis, and showed an improvement in the skin lesions. The benefits derived from Antistine appear to be the neutralization of the allergic end products and the symptomatic relief which facilitates healing. This was evidenced in those cases where blepharitis, atopic urticaria, and contact dermatitis were manifest.

The therapeutic response indicates that the hordeola, chalazions, ulcerative blepharitis, and acute conjunctivitis found in some of these patients, and usually classified as allergic entities, are not allergies per se, but are bacterial or mechanical complications. In effect, these conditions are the result of an infectious invasion on a fertile allergic soil. This was demonstrated by the fact that the aforementioned complications did not respond to Antistine until after the antibiotics or chemotherapy resolved the superimposed pathologic condition. In these cases, the combined use of Antistine with penicillin, sulfathiazole solution, or any of the ocular bacteriostatics would be advisable. Antistine was found to be compatible with most other ophthalmic drugs.

Analysis of the cases, in which Antistine ophthalmic solution proved of no value, revealed marked hypersensitivity to house dust. Of the 50 patients treated in the five groups, only 8 were unresponsive to the solution. Of these, two experienced side reactions and refused to continue treatment. Three patients had squamous blepharoconjunctivitis, of whom two were markedly positive to scratch tests with house dust. Of the remainder one patient had bulbar conjunctival serous cysts, another had palpebral pruritus, and the third had atopic palpebral dermatitis, with hypersensitivity to house dust.

Impressive was the favorable symptomatic response obtained in the four cases of vernal catarrh. Although no improvement in the pathologic state was noted, and despite the necessity for 4 to 5 instillations daily, these patients were grateful for the relief afforded by the Antistine.

In a number of the cases of atopic palpebral urticaria and contact dermatitis, the Antistine solution was supplemented with the application of Antistine ointment to the skin of the lids, resulting in an enhanced therapeutic effect. It is noted that relief was obtained more readily in the cases of acute urticaria and contact dermatitis than in the chronic lesions. In one case in this group, locally applied Antistine increased the itching sensation. In another, a case of angioneurotic edema, the Antistine was at first dramatically effective but the efficacy rapidly decreased. In the cases of this series (group 5), it was necessary to supplement local treatment with the oral administration of Antistine before the desired therapeutic effect was achieved.

It is stressed that all these cases were primarily extraocular allergies, that no effort was made to treat intraocular allergic conditions except as incidental or intercurrent, and that Antistine locally has great value in relieving the symptomatic manifestations of ocular allergy. The therapeutic value of Antistine is its ability to neutralize the effect of the liberated end-products of hypersensitive (allergic) states, locally as well as systemically, and to facilitate healing by diminishing the irritative phenomena of allergy.

Conclusions

1. The antihistaminic chemical drugs and their action are briefly reviewed.
2. Presented are 50 cases of ocular allergy and their response, symptomatically and therapeutically, to a new antihistaminic ophthalmic solution.
3. Antistine ophthalmic solution (Ciba) is advocated for use in the symptomatic relief of patients with extraocular allergy.

OCCLUSION OF THE CENTRAL RETINAL ARTERY*

A Clinicopathologic Study

A. L. Kornzweig, M.D.
New York

The opportunity to report on a case of occlusion of the central artery of the retina that was seen clinically and studied pathologically comes but seldom. Such a case is the subject of this report.

Clinical Study

Case Report

History. The patient, M. R., a woman, aged 72 years, was seen on August 4, 1943, with the history of a sudden loss of vision in the right eye. She was an inmate of The Home for Aged and Infirm Hebrews and her eyes had been examined several times before this occurrence. The vision in each eye had been 20/30 with correction. Clinically, the patient suffered from severe essential hypertension, the blood pressure ranging from 200/110 to 260/140 mm. Hg.

The patient had been watching a moving picture when she noticed the sudden loss of vision in the right eye. Examination shortly thereafter revealed the typical picture of a complete occlusion of the central retinal artery. The arteries were markedly attenuated. There was a gray edema of the macular area and the cherry-red spot in the fovea. Vision was reduced to light perception only in the temporal area. In the left, or unaffected eye, the fundus showed hypertensive retinal arteries. They were narrowed, tortuous, had an increased central light reflex, and completely obliterated the vein at the point of crossing. No hemorrhages or exudates were present in either eye.

Treatment. All attempts to improve the condition of the right eye were unavailing. These included massage, inhalation of amyl nitrite, sodium nitrite intravenously, and nitroglycerin by mouth.

Course. The patient was observed at irregular intervals for the next few years.

* This investigation was made possible by the Research Fund of The Home for Aged and Infirm Hebrews. Presented at the New York Society for Clinical Ophthalmology, October 6, 1947.

On October 29, 1943, the vision in the right eye was still only light perception. The pupil was fixed in mid-dilatation and did not react to light. The fundus could be clearly seen. The retinal arteries were narrowed almost to the point of obliteration. Perivascular sheathing of the larger branches of the central retinal artery was the temporal region. The fundus showed optic atrophy, with shaggy, uneven disc margins, attenuation of the arteries, narrowing of veins, and more perivascular sheathing. The cystlike appearance of the right macula was unchanged.

On September 16, 1945, the patient was admitted to the infirmary and died Septem-

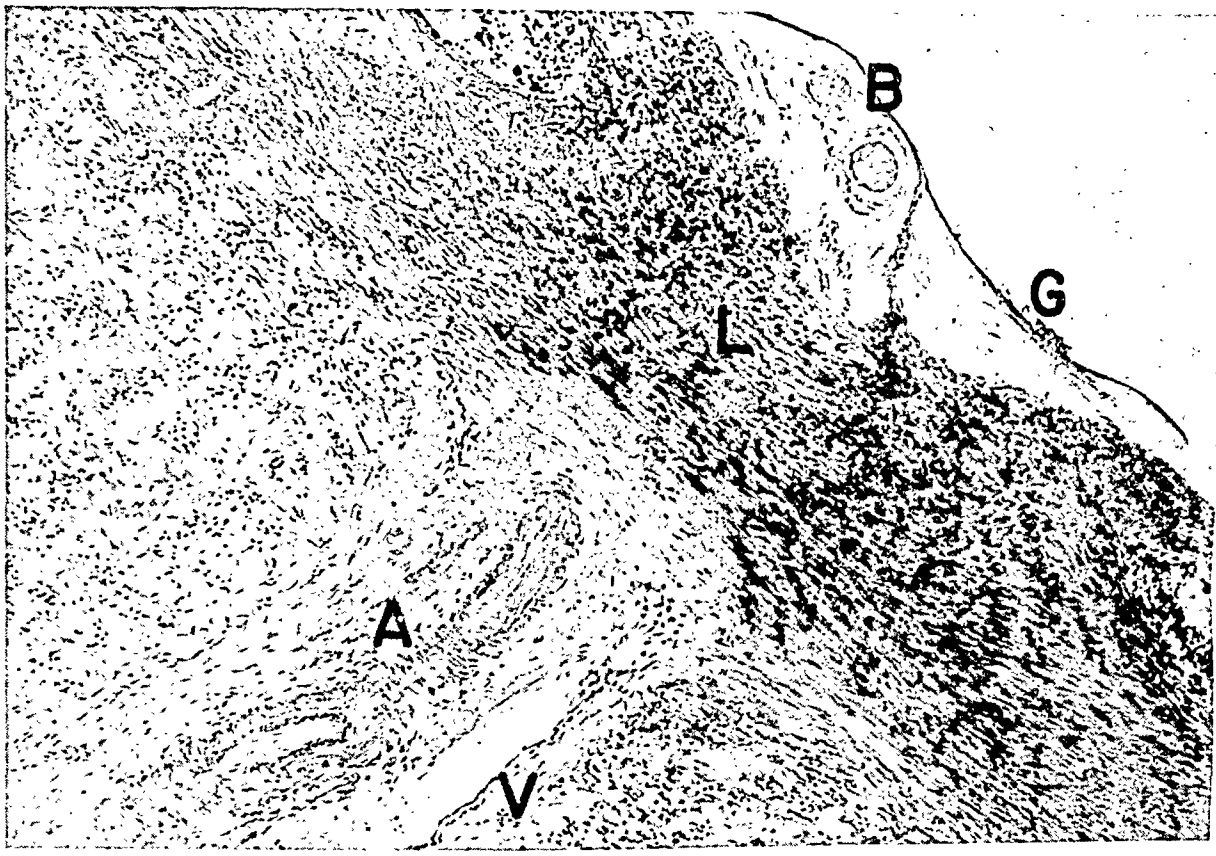

Fig. 1 (Kornzweig). Cross section of optic nerve and disc. The central retinal artery (A) and vein (V) are in the optic nerve before the lamina cribrosa (L). Branches (B) of the artery are on the disc, which is covered by glial tissue (G).

noted. Edema of the macular region was still present.

On February 19, 1944, the optic nerve of the affected eye had become pale and atrophic. The edema of the macula had disappeared and left a mottled appearance of the tissues in this region. A small, cystlike body was forming in the fovea. On August 4, 1944, the condition of the fundi was still the same.

On March 1, 1945, the vision in the right eye remained at light perception in

ber 17, 1945. This was a little more than two years after the occurrence of the occlusion of the central retinal artery in the right eye. Autopsy was performed on September 18, 1945, and both eyes were removed. Fixation of both globes was done in Bouin's solution. They were embedded in celloidin for several months. The right eye was cut horizontally in such a way that the entire nerve-head and optic nerve were completely in one half of the sectioned eye. Serial sections were made through the entire thickness of

optic nerve and disc and stained with hemotoxylin and eosin. Several slides, which showed the vessels chiefly in the optic nerve, were stained with Weigert's elastic stain.

Pathologic study

Several of the most important slides were photographed and are here presented.

Figure 1. The optic nerve and the disc can be seen in this figure. The central retinal vessels in the optic nerve and a few branches on the head of the disc are clearly seen. Between the two, the lamina cribrosa stands out as a darkly staining tissue. The artery in the nerve is definitely narrowed. In places its lumen can be seen. Near the lamina, the lumen of the artery appears to be narrowed, almost to the point of occlusion. The vein alongside of the artery is patent, but narrower than normal. On the head of the disc, and covering the physiologic cup, is a sheath of glial tissue. The two small vessels seen on the disc appear to be filled with blood. The lumen stands out fairly well and the endothelial lining is, apparently, intact.

Figure 2. This figure shows the central retinal artery in its entirety as it passes through the lamina cribrosa. The walls of the vessel are thickened, but its lumen appears to be intact. There is a constriction in the artery as it passes through the lamina cribrosa just before it arrives on the head of the disc. A small branch is given off from this vessel on the head of the disc. This small branch also is filled with blood and has a very narrow lumen. There is a possibility that this may indicate a recanalization of a closed vessel.

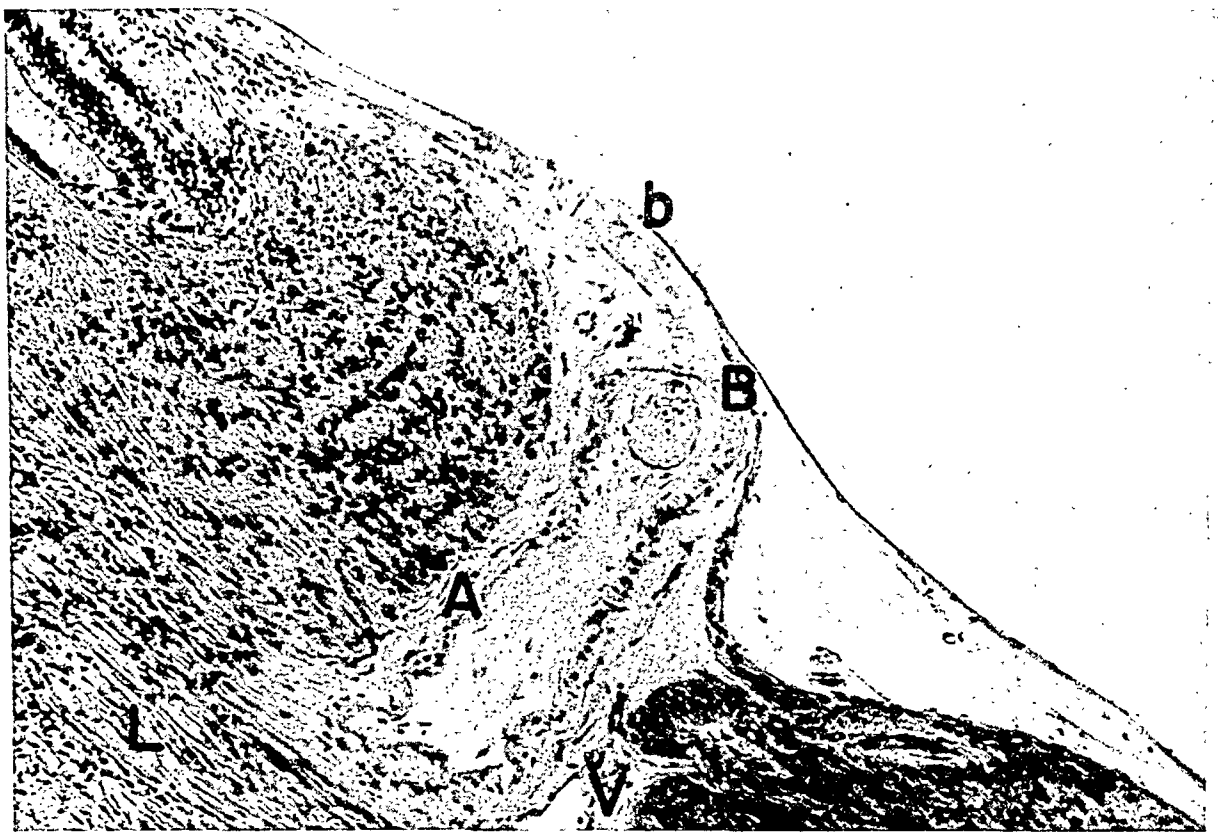

Fig. 2 (Kornzweig). Cross section of lamina cribrosa and optic disc. The central retinal artery (A) appears to be patent from the lamina (L) to the head of the disc. The media of the vessel is thickened. The endothelial lining of the branch (B) on the disc is intact. The smaller branch (b) may indicate recanalization of an occluded artery.

Figure 3. This slide is a section of the optic nerve only, which has been stained with Weigert's elastic stain. It shows the artery and the vein in their fibrous sheath. The artery stains rather heavily with the Weigert stain. Its lumen shows a moderate amount of debris and a small mass of elastic tissue to one side. This may indicate a proliferation of the elastica interna and, perhaps, the site of an occluding thrombus. The adjacent vein is widely opened and clear.

Figure 4. This slide is another section farther down, showing the same blood vessels, but in this case the lumen of the artery, although narrowed, appears to be entirely patent.

Figure 5. This slide shows the region of the macula in the affected eye. The ganglion cells in this region, and also the cells of the inner nuclear layer of the retina, are markedly reduced in number. The nerve-fiber layer is almost entirely absent. Even the cone-cell layer, directly in the foveal region, shows a thinning and a diminution in number of cone nuclei. In the subjacent choroid, several large veins and one artery can be seen. The artery has a very thickened wall and a narrowed lumen. This indicates advanced sclerosis of the choroidal arteries.

Figure 6. This shows a portion of the retina adjacent to the temporal side of the optic nerve and approaching the macula. That portion of the retina close to the optic nerve shows all the layers of the retina fairly intact. The nerve fibers are numerous and the ganglion cells are present, as well as the cells of the internal nuclear layer. There is a definite transition from normal retina to atrophic retina, which is fairly sharp. This

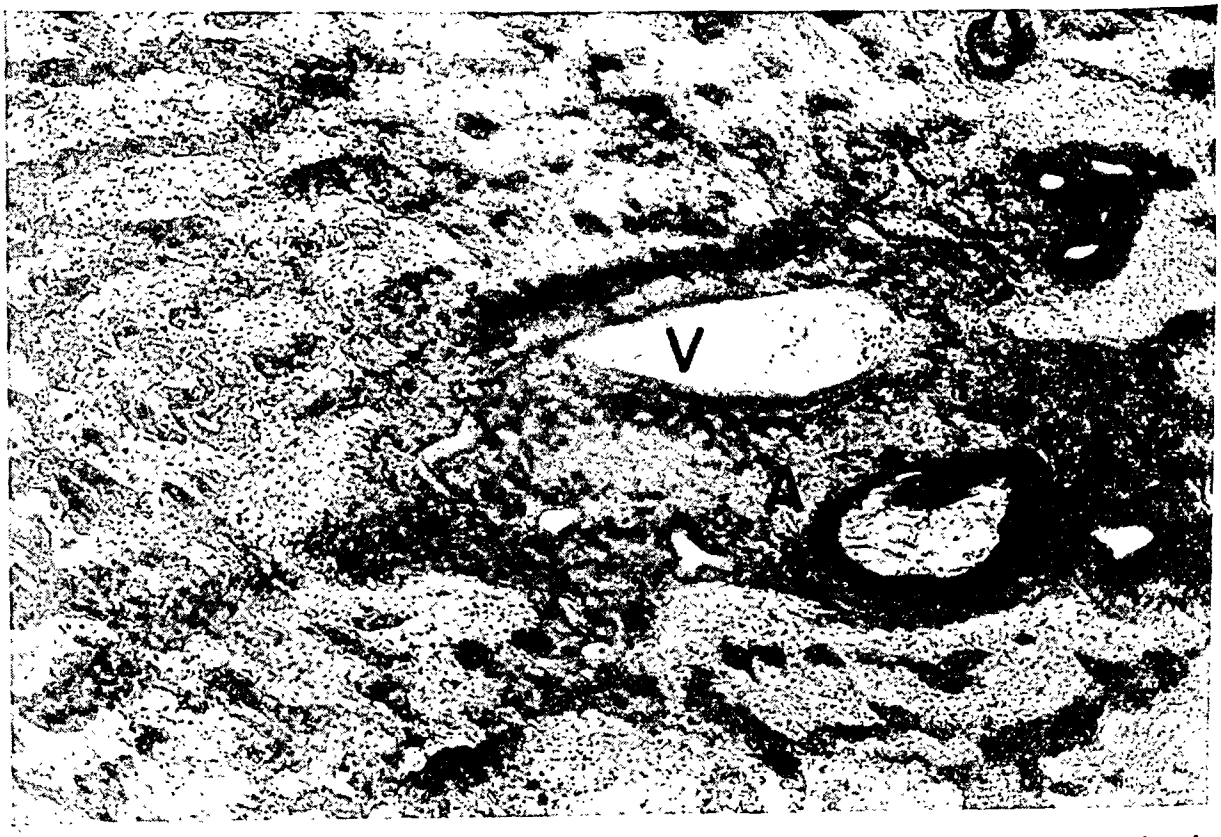

Fig. 3 (Kornzweig). Cross section of portion of optic nerve under high power, stained by Weigert's elastic tissue stain. The central retinal artery (A) shows heavy elastic tissue staining with debris in the lumen. The vein (V) is normal and patent.

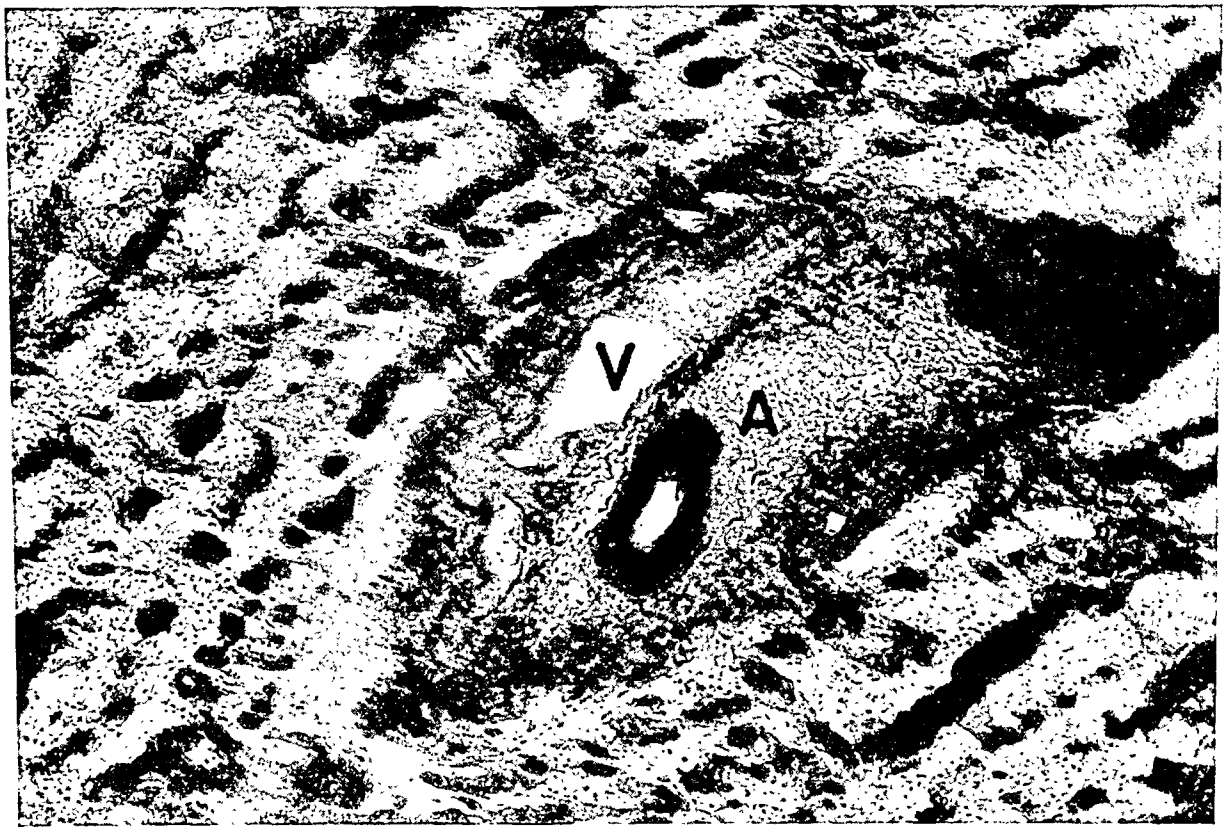

Fig. 4 (Kornzweig). Cross section of portion of optic nerve under high power, Weigert's elastic tissue stain. The central retinal artery (A) has a thickened elastica interna, but its lumen is patent.

transition shows the point of division between that portion of the retina which still has a fairly good blood supply and that portion to which the blood supply has been diminished because of the occlusion of the central retinal artery.

Figure 7. This is a cross section of the optic nerve of the unaffected eye. It gives a very clear picture of the central retinal artery in several sections, both in the nerve and on the disc. There is some thickening of the walls of the central retinal artery, but its lumen is clear and patent throughout. There is no evidence of much endothelial thickening or proliferation of the elastica interna. The vein is normal throughout. In addition, on the head of the optic nerve, the physiologic cup is seen and there is no glial proliferation as in the affected eye.

It would have been preferable to section the eye at right angles to the nerve and the central retinal artery and vein. These slides, therefore, are not conclusive. They do, however, show narrowing of the central retinal artery and an irregular, uneven lumen. A complete obliteration or occlusion of the central retinal artery is not present. Occlusion of the artery by a so-called embolus also cannot be seen. One may speculate on what the passage of time may have done to a soft thrombus in the artery. The possibility of occlusion of the vessel by spasm must also be considered.

Discussion

The earlier reports on this subject considered chiefly organic changes in the artery or embolus as the cause of the occlusion. These are reviewed fully by Parsons,[1] Duke-Elder,[2] Coats,[3] Collins and Mayou,[4] and Bridgett.[5] Von Graefe, who reported the first case of embolus of the central retinal

artery, gave, as the possible causes, endocarditis with valvular incompetence, arteriosclerosis or aneurysm of the carotid system.

Coats contributed a report reviewing 26 cases in 1905, and added several of his own. An embolus was not shown in many cases. He gave as the most common causes of occlusion, endarteritis and thrombosis of the central retinal artery. Other theoretical causes were also mentioned, for which there was no pathologic evidence. These included: (1) Retrobulbar neuritis, (2) hemorrhage within the optic nerve or its sheath; (3) tumors of the optic nerve; and (4) spasm of the arteries. Spasm was mentioned as being due, possibly, to quinine poisoning or Raynaud's disease.

More recently, spasm of the central retinal artery has been stressed as causing occlusion, which may lead to temporary or permanent loss of vision in the affected eye. Kravitz[6] cites three cases of temporary visual loss due to spasm of branches of the central retinal artery in two, and a cerebral artery in the third. One of these cases had a permanent paracentral scotoma. Duke-Elder[2] and Elwyn[7] also give considerable importance to spasm as a cause of occlusion. Sedan and Jayle[8] reviewed the subject of spasm of the central retinal artery. They mention the possible causes contributing to spasm as: (1) Migraine and vasomotor instability, (2) hypertension and arteriosclerosis, (3) Raynaud's disease, (4) severe hemorrhage, (5) poisons (quinine, tobacco, coffee, and barbituric acids), (6) glaucoma, (7) polycythemia, (8) epilepsy, and (9) papilledema.

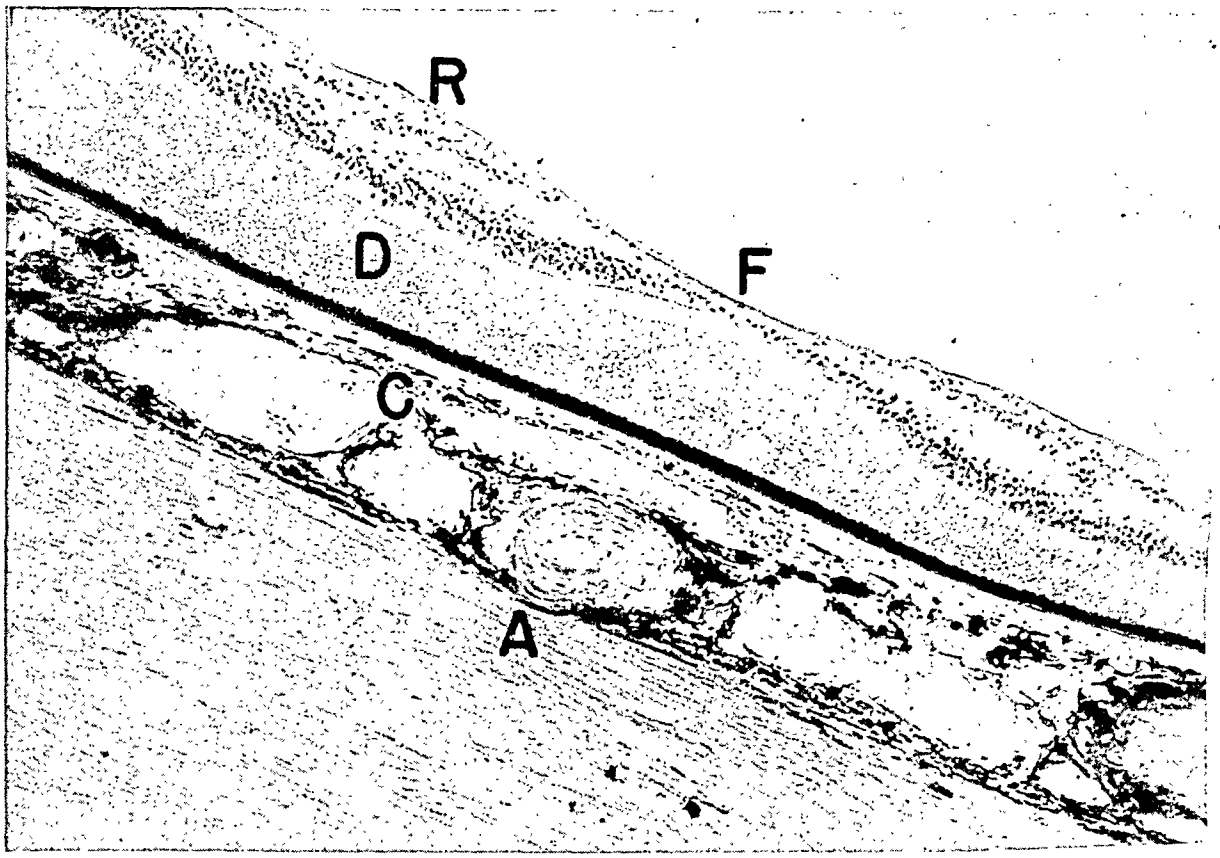

Fig. 5 (Kornzweig). Macula region of retina. Inner layers of retina (R) and fovea (F) are atrophic. There is subretinal fluid or debris (D). In choroid (C) a sclerotic artery (A) is prominent.

In the case here reported, I am inclined to believe that spasm of the central retinal artery played a large part in the blocking of the vessel. While sclerosis of the arteries in the choroid and in the central retinal artery is present, there is very little evidence of atheromatous degeneration in the blood vessels around the eye.

The postmortem examination of the heart showed normal opening of the coronary arteries. The blood vessels along their course showed a slight degree of narrowing, due to deposition of atheromatous plaques, but there was no obstruction to the flow of blood. The endothelial lining appeared to be intact throughout.

There is no evidence of complete blocking of the central retinal artery by an embolus or an occlusive thrombus. There is also no evidence of recanalization of an occluded vessel. Against the consideration of spasm as the whole cause of occlusion of the artery is the clinical evidence of the observation of the patient from the time of occurrence of the incident until her death. The artery remained narrowed throughout the entire period of observation, and was never seen to dilate or return to a normal condition.

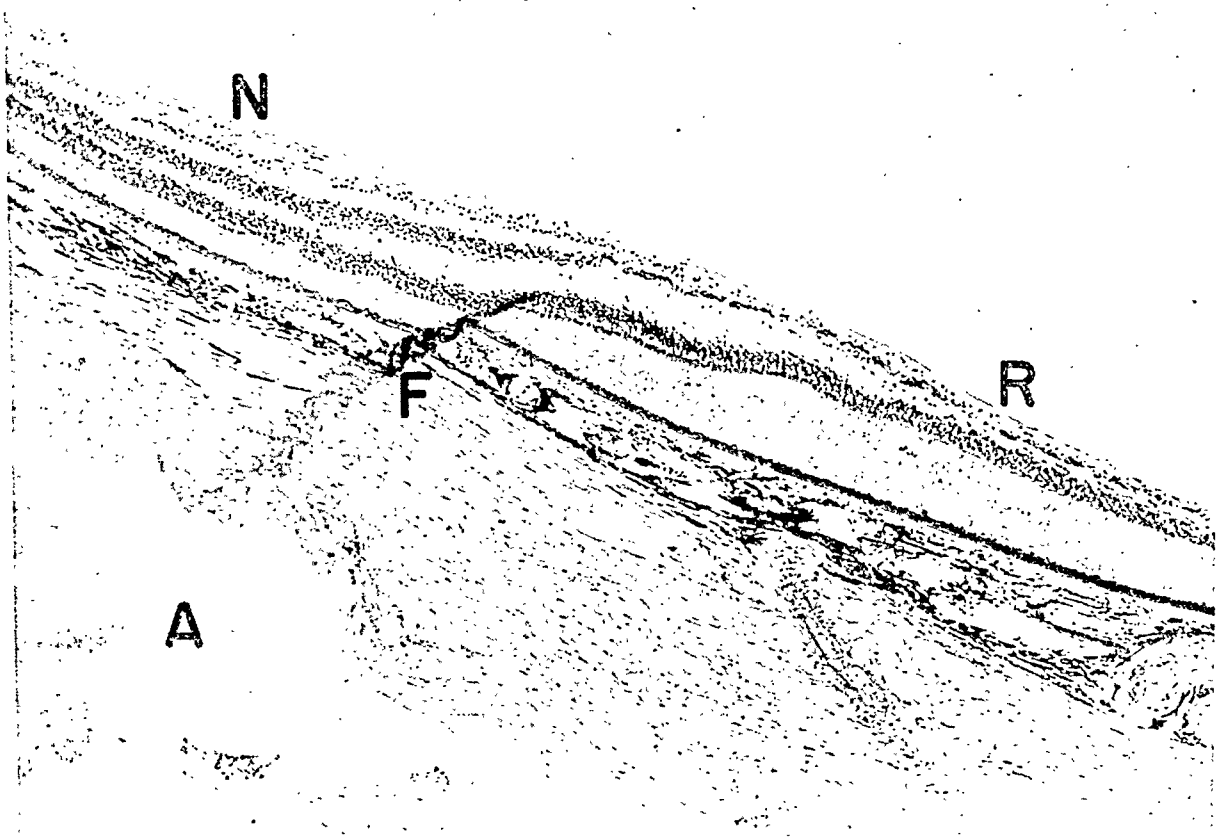

Fig. 6 (Kornzweig). Section of retina near optic disc. The normal retina (N) is near the disc. It changes to atrophic retina (R) rather sharply. (F) is a fold in the tissue, and (A) is an artifact.

Summary and Conclusions

A case of occlusion of the central retinal artery in a woman, aged 72 years, is presented. She suffered from essential hypertension of moderately severe degree. The patient was followed for over two years until

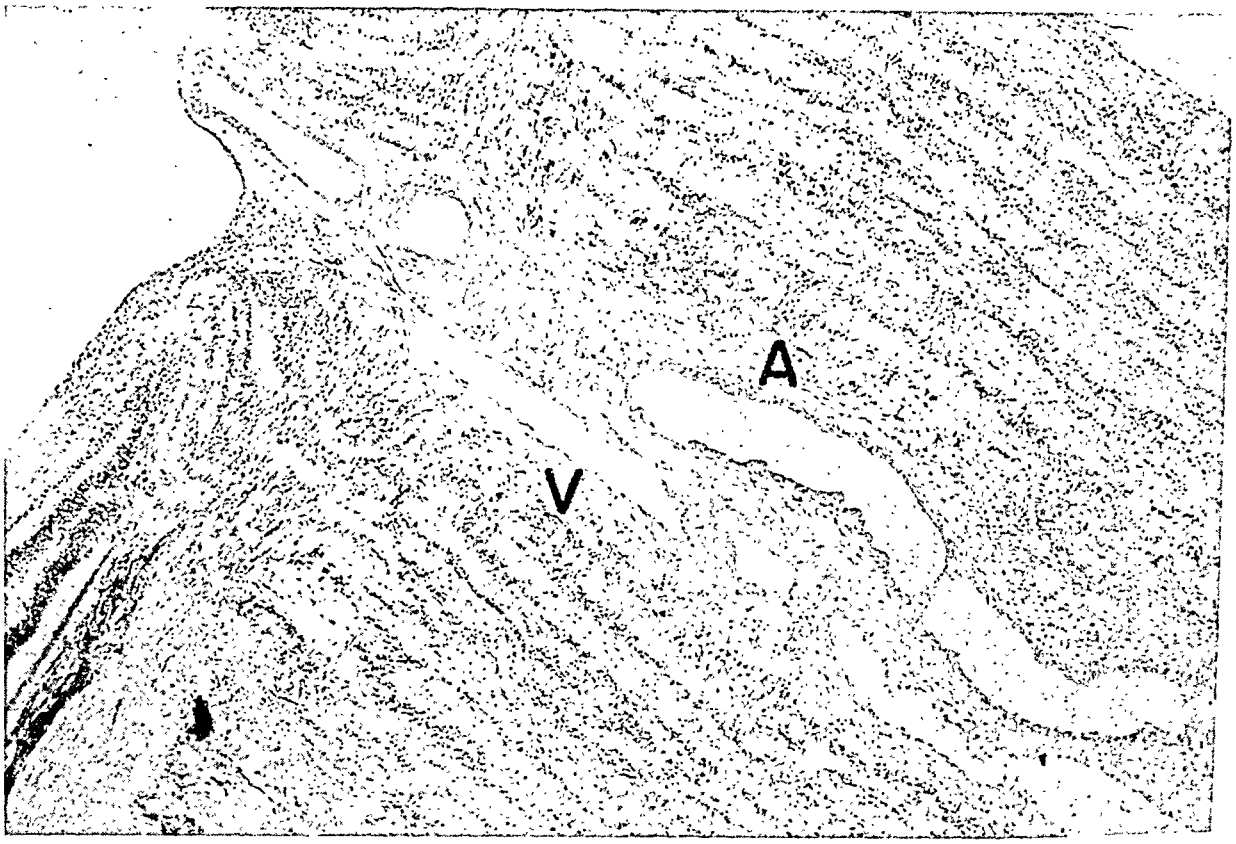

Fig. 7 (Kornzweig). Cross section of optic nerve and optic disc in the normal eye. The central retinal artery (A) and vein (V) are seen in several segments and are patent throughout.

her death, at which time the eyes were examined pathologically. No evidence of embolus, thrombus formation, or endarteritis was found. Advanced arteriosclerosis was present in the choroidal and central retinal arteries. Spasm is considered as contributing to the occlusion of the central retinal artery.

1200 Fifth Avenue (29).

I wish to express my appreciation to Dr. David Wexler for his help in the interpretation of the slides.

EFFECT OF MUSCULAR EXERCISE ON DARK ADAPTATION*

JOHN P. WENDLAND, M.D.
Minneapolis, Minnesota

INTRODUCTION

Muscular exercise is one of the most important and most frequently encountered stress situations, and investigations of its effect on the dark-adaptation process is of considerable interest for various reasons. Muscular exercise, even of moderate intensity, produces pronounced metabolic, circulatory, and respiratory changes and thus presents a useful method of studying the effect of these changes upon one of the most fundamental visual functions. Also, in situations where muscular exercise occurs in darkness, or prior to the entrance of an individual into darkness, the problem has obvious practical applications. In addition, any effect muscular exercise has on dark adaptation would be important in the standardization of dark-adaptation tests.

In view of the large amount of research work performed during recent years on the effect of various factors influencing dark adaptation, one would expect a substantial number of publications dealing with the effects of muscular exercise. Actually, the literature is meager; only two articles could be found dealing with this subject.

Bodansky and Hendley[1] found that bicycle ergometer exercise both in normal and methemoglobinemic individuals produced a rise in the rod thresholds after 5 to 10 minutes. However, the methemoglobinemic individuals showed an improvement in sensitivity preceding the depression; whereas, the normal individuals showed no improvement at any time. There was no correlation between the amount of work done, which ranged from 20,000 to 35,000 foot pounds over a period of from 3 to 5 minutes, and the changes in threshold obtained.

Kekcheev[2] claimed that light muscular exercise reduced the duration of the dark-adaptation process from 25 to 45 minutes to 5 to 6 minutes; such a claim is surprising, as no other factor affecting dark adaptation has been noted to influence it to a comparable degree. His article is very brief, however, and does not give any details of his method.

METHOD OF INVESTIGATION

A biophotometer was used but the technique of its use modified. The test area in this instrument normally consists of a quincunx of spots, the illumination of which may be varied by means of a rheostat adjusted by the examiner. Filters are present in the instrument which make the light intensity of the two left-hand spots the highest, the central spot of medium intensity, and the two right-hand spots of least intensity. The subject reports on any given threshold when he is able to distinguish the central and two left-hand spots of the quincunx, but not the two on the right.

Considerable justified criticism[3-5] has been leveled at the results obtained with this instrument, as it has been used by various investigators. The major fault has been the lack of a fixation spot. This fault, however, is readily corrected by using the instrument according to the method first described by Sheard,[6] and this technique was followed in these experiments. All spots, except the upper-left and central spot, were covered with opaque adhesive tape. The subject fixes on the upper-left spot and reports on the appearance of the central spot as the brightness of both is increased. The change in wave length of the test light[3] as the spots are dimmed is of no consequence in these studies since the same wave-length change is present both in the controls and in the tests following exercise.

* From the Department of Physiological Hygiene and Division of Ophthalmology, University of Minnesota Medical School.

The preadapting light incorporated in the biophotometer is of insufficient brightness to record the full extent of the visual adaptation curve. A brighter preadapting light, as mentioned below, was, therefore, used.

The left eye was used in all determinations; the test spot subtended an angle of one degree, 6 degrees temporal and superior to the fovea.

The influence of light and heavy muscular exercise on both the rate and final rod threshold of adaptation was studied. The experimental arrangement and testing procedure are summarized in Table 1. In the light-exercise experiments, in order to make the work load physiologically comparable in various subjects of unequal muscular capabilities, exercise was performed at a rate which would increase the pulse rate by 25 to 30 beats per minute.

TABLE 1

SUMMARY OF METHODS OF TESTING THE EFFECT OF EXERCISE ON DARK ADAPTATION

Type of Exercise	Duration and Rate of Exercise	Procedure of Testing	Rate of Dark Adaptation or Final Threshold	No. of Subjects; No. of Tests
Light				
Bicycle ergometer	35 min.; pulse increase of 25–30 beats per min.	Exercise started immediately after preadaptation. Readings taken at 4, 8, 12, 16, 20, 25, 30, and 35 min.	Rate	9 subjects, 13 tests
Genuflexions	2½–3 min.; pulse increase of 25–30 beats per minute	Exercise started immediately after preadaptation. Readings taken at 4, 8, 12, 16, 20, 25, 30, and 35 min.	Rate	8 subjects, 8 tests
Bicycle ergometer	10 min.; pulse increase 25–30 beats per min.	Exercise started after full dark adaptation. Readings taken after exercise from 15 sec. to 13 to 15 min.	Final threshold	5 subjects, 6 tests
Genuflexions	2½–3 min.; pulse increase of 25–30 beats per min.	Exercise started after full dark adaptation. Readings taken after exercise from 15 sec. to 13 to 15 min.	Final threshold	7 subjects, 7 tests
Heavy				
Standing running	subject ran "all out" until exhaustion which in no case was more than 2½–3 min.	Exercise - started immediately after preadaptation. Readings taken at 4, 8, 12, 16, 20, 25, 30, and 35 min.	Rate	4 subjects, 4 tests
Standing running	subject ran "all out" until exhaustion which in no case was more than 2½–3 min.	Exercise started after full dark adaptation. Readings taken after exercise from 15 sec. to 13 to 25 min.	Final threshold	19 subjects, 20 tests

The subjects were all college students between the ages of 17 and 29 years, with no ocular defects. They were well trained on the apparatus in order to eliminate learning as a possible factor in the results obtained. In the experiments on the rate of dark adaptation, successive tests were made with no exercise in between to establish controls.

In the experiments on the final rod threshold, numerous readings were taken until the subject reached a level constant except for the slight unavoidable normal variability found in repeated readings. Exercise was then performed using the preëxercise read-

ings as controls. Only values exceeding the normal preëxercise variability are considered in this paper.

Statistical analysis of the results was accomplished by means of the "t-test" (Fisher[7]). The subjects performed no exercise, other than walking to the laboratory, for several hours prior to the tests and rested in a room, illuminated with 2 foot-candles, for 15 minutes before the control tests were begun.

Tests

In the tests concerning the effect of exercise on the rate of adaptation the subject was preadapted for a period of one minute to a light of 2,400 millilamberts subtending an angle of 41 degrees at the subject's eye. For light exercise two forms of exercise (bicycle ergometer and genuflexions) performed as indicated in Table 1 were used. For heavy exercise but one form of exercise (standing running all out) was used.

In the tests concerning the effect of exercise on the final rod threshold, exercise was begun after full dark adaptation. The same forms of exercise were used as in the experiments on the rate of dark adaptation.

Results

In tabulating the effects of exercise on the rate of adaptation, the readings taken during the course of adaptation are divided into 3 intervals. Interval I includes the readings at 4, 8, and 12 minutes; Interval II, the readings at 16, 20, and 25 minutes; and Interval III, the readings at 30 and 35 minutes.

The results of light exercise are shown in Table 2. Columns 5 and 9 represent the effect on the "total dark adaptation curve" (T.D.A.). The effect on the T.D.A. was arrived at by averaging the values of individual readings taken during the entire course of dark adaptation as given in Table 1. A plus value denotes an increase in sensitivity (lowering of threshold), and a minus value a decrease in sensitivity (rise in threshold), compared to control values. It will be noted that most of the changes

are of small magnitude and that they are both plus and minus. The statistical analysis of the results shows that light muscular exercise has no effect upon the rate of dark adaptation.

The effects of heavy exercise on the rate of dark adaptation are represented in Table 3. It will be seen here that, under Intervals I and II, the values fall fairly equally on both the plus and minus sides. In Interval III, however, all the values are minus except one and, in the column T.D.A., all values are minus. Statistical analysis shows that, although there is a tendency to a decrease in sensitivity in Interval III, which represents final rod thresholds, and in the T.D.A., none of the changes are of sufficient magnitude to reach statistical significance.

Table 4 represents the results of the experiments with the effect of light exercise on the final rod threshold—that is, on the threshold of the fully dark-adapted eye. It will be noted that there is a tendency to both a lowering and a raising of the threshold. The lowering of the threshold occurs immediately after exercise and is of comparatively short duration as shown in Column 3; it is followed by a rise in the threshold of

somewhat longer duration (column 6). However, the changes again are not statistically significant.

The effect of heavy exercise on the final rod threshold is seen in Table 5. In the majority of subjects, the reaction is biphasic; that is, there is a temporary improvement in sensitivity of short duration, followed by a decrease in sensitivity often of considerable magnitude and duration. Treated statistically the tendency shown in light exercise has here become highly significant. Superimposed upon the overall biphasic change are wavelike fluctuations of the threshold especially marked during the depression phase. These fluctuations are evident in Columns 3 and 6, Table 5.

There was no difference in the reactions between men and women. Sixteen out of 20 subjects showed some transitory improvement immediately following exercise; whereas, all showed a reduction in sensitivity beginning in 1 to 5¾ minutes following exercise and lasting from 1 to 16 minutes. The improvement immediately following exercise varied from none to 0.2 log units; the elevation of the threshold from 0.08 to 0.56 log units. Thus, considerable individual variability was present. The maximum decrease in sensitivity of 0.56 log units represents almost a fourfold change in sensitivity. The mean lowering of the threshold was 0.08 log units with a mean duration of ⅔ minutes; the mean rise of threshold was 0.26 log units with a mean duration of 5¾ minutes. In two subjects, pilocarpine fixation of the pupil was used and in one, an artificial pupil. Control of pupillary size in this manner in no way influenced the response of the subject to the exercise.

Therefore, pupillary reactions cannot play a part in the results found.

Figure 1 represents graphically the response to heavy exercise. It will be seen that actual average magnitude, for it was computed by averaging the values of all the subjects at given time intervals following the exercise. As the subjects showed considerable variability in the time of occurrence of the depression phase the general effect of averaging their values would be to level off the curve. This biphasic response is somewhat similar to the effect of muscular exercise on the fusion frequency of flicker.[8]

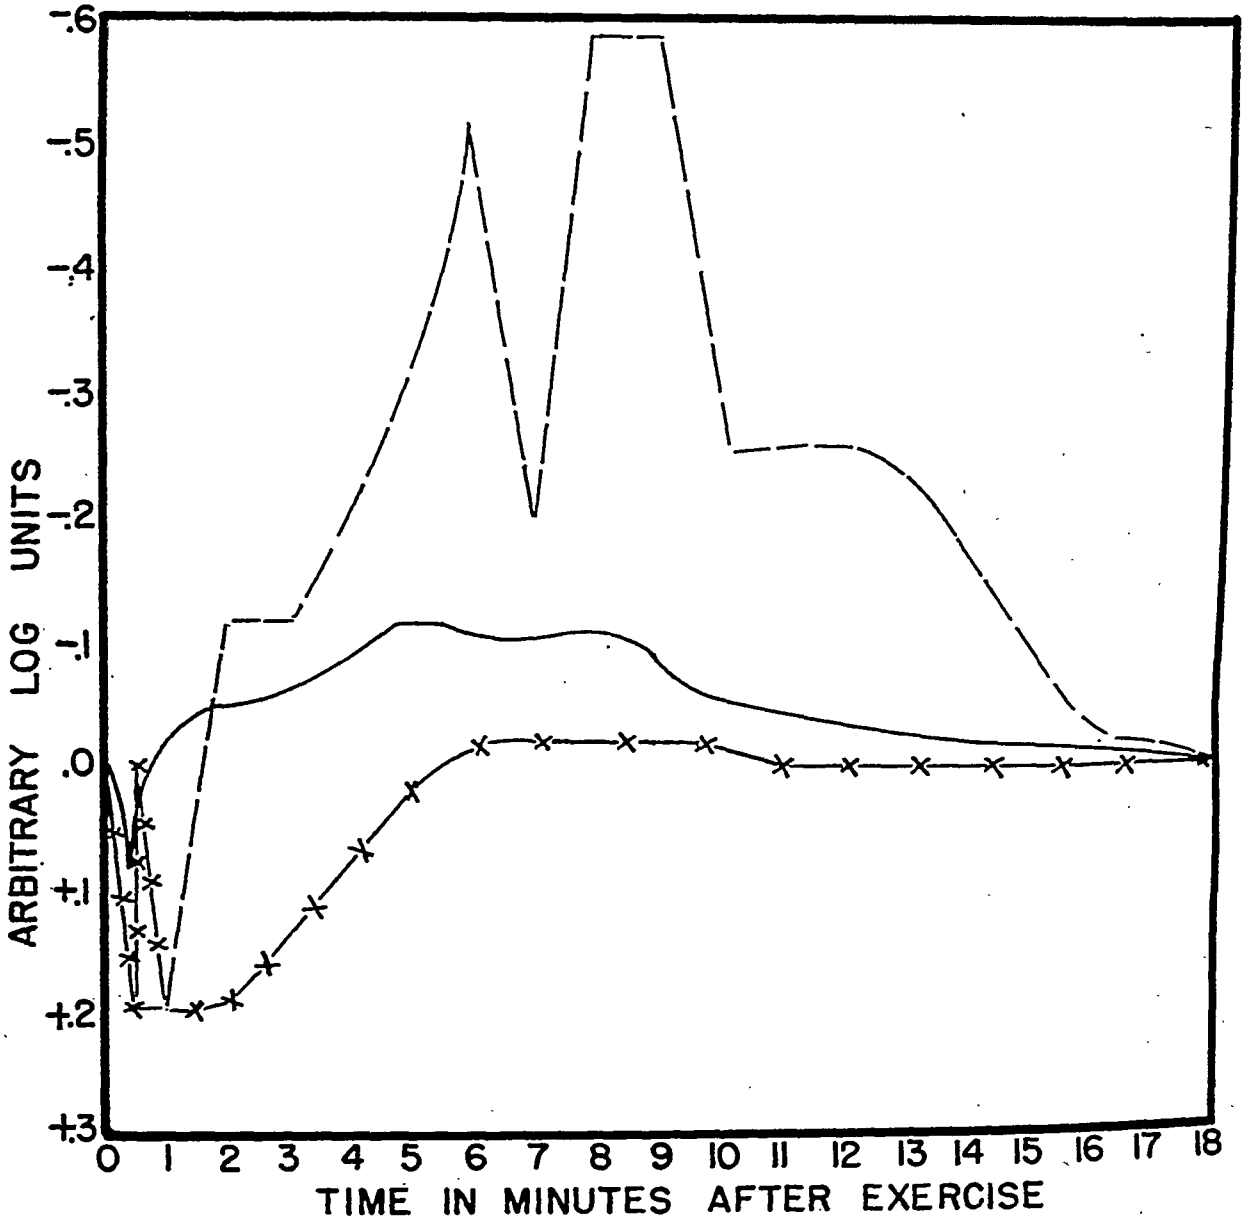

Fig. 1 (Wendland). Effect of heavy exercise on the final rod threshold. "O" represents the threshold level before exercise. Minus (—) values denote a rise in the threshold, plus (+) values a lowering of the threshold. –x–x– Subject showing maximum lowering of the threshold. – – – Subject showing maximum rise of the threshold. ——— Mean of all subjects.

the rise in threshold is much more marked and extends over a longer time interval than the lowering of the threshold. The curve showing the mean response is of value mainly for showing the general biphasic character of the response rather than the

In none of the tests was any correlation found between the physically trained and untrained subjects.

Discussion

The following factors may be concerned in the production of the changes in dark adaptation following exercise:

1. In muscular exercise, an irradiation of impulses from motor centers to other parts of the nervous system is generally assumed. This is thought to be responsible for the marked change in respiratory rate which occurs immediately after exercise before any blood changes could have reached the respiratory center.[9] This irradiation continues throughout exercise and may be responsible for the lowering of thresholds immediately following exercise.

2. The increased blood flow during exercise may improve the blood supply of the retina and brain, a factor which possibly would tend to lower thresholds.

3. The oxygen debt found in heavy exercise is possibly the major factor in causing an elevation of thresholds. All investigators are agreed that reduced oxygen tensions, such as those caused by high altitude, cause an elevation of thresholds.[6, 10-14] It would seem at first glance that the oxygen debt in muscular exercise acted in an exactly similar manner. However, the physiology of the two situations is different. In anoxia there is reduced oxygen saturation of arterial blood; whereas, in muscular exercise the blood becomes properly oxygen saturated as it passes through the lungs. Thus in muscular exercise, the brain and eyes possibly do not receive a diminished oxygen supply. Nevertheless, the oxygen debt does express a need of oxygen by the organism and it is probably in some measure responsible for the elevated thresholds following muscular exercise. The maximum depression in the final rod threshold following exercise, as noted above, was 0.56 log units, or a change equal to the effect produced by an altitude of approximately 15,000 feet.

4. Wald and associates[15] have shown that the addition of 5-percent carbon dioxide to the air an individual at rest inspired elevated the final rod threshold from 0.2 to 0.5 log units (approximately a 1⅔ and threefold change, respectively). Conversely, washing out of carbon dioxide by breathng room air at rates 50 to 100 percent more rapidly than normal caused a lowering of the threshold of about 0.27 log units. Thus according to Wald *et. al.*, respiratory acidosis and alkalosis exert opposing effects upon the visual threshold. Possibly the increased production of carbon dioxide and acidosis found in severe exercise may contribute to the elevated thresholds noted following exercise.

It is interesting to note that most of these same factors have been used to explain the changes observed in the fusion frequency of flicker following exercise.[8]

The coexistence and temporal relationships of these factors in exercise are responsible for its effects on dark adaptation. The depressing effect of heavy exercise is of importance in tasks performed at night and requiring good night vision—for example, night flying.

In general, the findings of Bodansky and Hendley[1] have been confirmed, although some differences are noted. In contrast to our observations, they were unable to demonstrate a significant improvement in normal individuals shortly following exercise. Likewise, they found no correlation between the amount of exercise and the depression of sensitivity obtained. In the experiments reported in this paper, normal individuals showed a statistically significant improvement in rod thresholds immediately following exercise followed by a depression of sensitivity similar to that obtained by Bodansky and Hendley. Also in my experiments, there is correlation between the severity of the exercise and the effects produced; light exercise produces both a smaller improvement and depression phase than does heavy exercise.

Kekcheev's results have not been confirmed.

It is suggested that as part of the standardization of dark-adaptation testing, investigators limit the physical activity of their subjects for one-half hour prior to testing.

Summary

Twenty-nine subjects were used, on whom 60 tests were performed, in studying the effect of light and heavy muscular exercise upon both the rate and final rod threshold of dark adaptation.

Light exercise has essentially no effect upon the rate of dark adaptation and only a tendency to produce a slight biphasic response in the rod threshold. For practical purposes it may be said to exert no effect on dark adaptation.

Heavy exercise produces a tendency to elevation of the thresholds of the total dark-adaptation curve and causes a marked biphasic response in final rod thresholds. The biphasic response consists in, first, a lowering of the threshold of short duration, followed by a rise in the threshold, often of considerable magnitude and of longer duration. In one subject, the depression of sensitivity was equal to that produced in an individual at an altitude of 15,000 feet. In practical application, heavy exercise may be said to produce a definite decrease in ability to see at night.

The factors responsible for these observations have been discussed and the importance of the changes in critical visual tasks performed at night pointed out.

The Medical School (14).

POSTOPERATIVE HYPERTROPIA*

RICHARD G. SCOBEE, M.D.
St. Louis, Missouri

Hypertropia which is first recognized following the surgical correction of either esotropia or exotropia is familiar to every ophthalmic surgeon and orthoptic technician. It is, in fact, a frequent source of chagrin to the conscientious surgeon. The commonly accepted explanation is that the surgeon when reinserting one or both of the horizontal rectus muscles selected a new site which was either above or below the horizontal meridian of the globe.

If it had been the intent of the operator either to recess or advance the point of insertion of a muscle and yet keep that muscle's line of pull unchanged, the appearance of a vertical deviation following surgery would be an obvious source of embarrassment. An occasional surgeon is too surprised to comment while the more intellectually honest one, in speaking of a postoperative hypertropia, sadly concludes "... I must have gotten a muscle too high!"

VERTICAL DEVIATIONS

Before going further into the subject, it would be worthwhile to consider how much vertical deviation it is possible to produce by purposely reinserting the horizontal rectus muscles either above or below the line of their original insertions. Foster and Pemberton (1946) reported results in a series of 26 patients in whom they had purposely raised or lowered the insertion of one of the horizontal rectus muscles. Their results, cited in the next paragraph, represent the averages for the various forms of correction found in the series.

LATERAL RECTUS

Whole width raising with resection and advancement	11.2$^{\Delta}$
Whole width raising with resection	7$^{\Delta}$
Half width raising with resection and advancement	9$^{\Delta}$
Half width raising with resection	5.4$^{\Delta}$

MEDIAL RECTUS

Half width raising	2.75$^{\Delta}$

They concluded that ". . . there is some justification for such a procedure when the vertical error is constant and less than 11 prism diopters at all horizontal angles."

The significance of this study with respect to the present line of thought is inescapable. It is entirely possible that a surgeon might erroneously reinsert one of the horizontal rectus muscles a millimeter or so too high in operating on these muscles. It is almost beyond the realm of possibility, however, that one could erroneously reinsert one a whole width (10 mm.), or even a half width (5 mm.) too high. And even if such an erroneous reinsertion were made, the maximum resultant deviation would not be more than 11 prism diopters!

The "mysterious" vertical deviations which "appear" following surgery on the horizontal rotators are frequently of an order greater than this 11 prism diopter maximum, particularly in lateral directions of gaze. The conclusion is therefore forced upon us that one could not possibly produce many of these observed postoperative vertical deviations by working only on the horizontal rotators even if one tried to do so!

An intentional vertical effect may be so produced but its magnitude is relatively small—that is, 11 prism diopters at a maximum. True postoperative hypertropia in surgery of the horizontal rotators alone is

* From the Department of Ophthalmology, Washington University School of Medicine and the Oscar Johnson Institute, St. Louis. Part of a study made under contract with the Office of Naval Research as Project N6onr-202, Task Order I, NR 141-022. Read before the sixth annual meeting of the American Association of Orthoptic Technicians, Chicago, October 12, 1947.

always the intent of the surgeon and will seldom if ever exceed 11 prism diopters even in lateral directions of gaze.

If, as has been indicated in the reasoning so far, true postoperative hypertropia is almost invariably the intent of the surgeon and is otherwise quite rare, then all other hypertropia recognized postoperatively must also have been present preoperatively!

It would be more correct to say that the reason for the existence of this type of postoperative hypertropia was present preoperatively but was hidden, for one reason or another, from the casual observer. How is this possible? The explanation is usually simple and is to be found in a brief review of the mechanics of the oculorotary muscles.

Mechanics of oculorotary muscles

Each of the six oculorotary muscles has a primary action when contracting in moving the globe from the primary position. Secondary actions, when present, exist solely because the line of pull of the particular muscle makes an angle with the optic axis of the globe instead of coinciding with it.

Medial rectus

As examples of these widely known facts, consider the medial rectus muscle and the superior rectus muscle. The line of pull of the medial rectus coincides with the optic axis of the globe when the eye is in the primary position. The medial rectus, therefore, has a primary action of ADduction and no secondary actions when acting from the primary position.

Superior rectus

The line of pull of the superior rectus, on the other hand, makes an angle of about 25 degrees with the optic axis in the primary position and its line of pull runs medial to the center of rotation of the globe; meanwhile, the superior rectus is inserted into the globe at a point anterior to this same center of rotation. Although contraction of the superior rectus from the primary position results principally in elevation, the angulation of its line of pull with respect to the optic axis and to the center of rotation is responsible for its secondary actions of ADduction and INtorsion.

When the line of pull of a muscle makes an angle with the optic axis of the globe and bears a certain relationship to the center of rotation of the globe, then that muscle has a certain mechanical efficiency in producing its primary and secondary actions from the primary position.

The superior rectus is most efficient, acting from the primary position, as an elevator (its primary action) although some of its power resulting from contraction is expended in producing the secondary actions of ADduction and INtorsion. Since its mechanical advantage as an elevator in the primary position is not perfect, its mechanical efficiency in elevation is less than 100 percent; indeed, Adler (1945) estimated it at 73.7 percent.

As the eye moves to assume various secondary and tertiary positions of gaze, the mechanical advantage of each oculorotary muscle changes and hence its mechanical efficiency also changes. As the globe is ABducted 25 degrees from the primary position, the line of pull of the superior rectus moves to coincide with the optic axis and when this occurs the superior rectus acts maximally as an elevator—its primary action—while losing entirely its secondary actions of ADduction and INtorsion.

On the other hand, if the globe is ABducted 65 degrees from the primary position, the line of pull of the superior rectus will make an angle of 90 degrees with the optic axis; it is an obvious mechanical impossibility for the superior rectus to elevate the globe when acting upon it through an angle of 90 degrees. The efficiency of the superior rectus as an elevator will have fallen to zero; meanwhile it can now act with great efficiency both as an ADductor and as an INtortor. So much for a brief review of the superior rectus.

Superior oblique

The superior oblique makes an angle of about 55 degrees with the optic axis when the globe is in the primary position, and its primary action is one of INtorsion; secondarily it is an ABductor and a depressor by virtue of its angular attachment with respect to the optic axis and to the center of rotation. In the primary position, the superior oblique is able to expend about 56.1 percent of its effort in producing INtorsion (Adler, 1945); the balance of its power is expended in producing its secondary actions of depression and of ABduction.

If the globe were ABducted 35 degrees from the primary position, the line of pull of the superior oblique would make an angle of 90 degrees with the optic axis; in such a position, the superior oblique would act maximally as an INtortor but would have lost entirely its secondary action of depression for obvious mechanical reasons.

On the other hand, if the globe were ADducted 55 degrees from the primary position, the line of pull of the superior oblique would coincide with the optic axis and that muscle would act maximally as a depressor and not at all as an INtortor.

Right esotropia

Consider a patient with 45 degrees of right esotropia who has a paretic right inferior rectus muscle. If paresis of the right inferior rectus were the only cause of any vertical deviation, one would expect a right hypertropia resulting from the partially unopposed action of the right superior rectus.

If a right esotropia is present in the amount of 45 degrees, the right inferior rectus paretic, and the right superior rectus therefore acting partially unopposed, nevertheless the expected right hypertropia would be almost if not completely hidden because the right superior rectus, even though acting partially unopposed, is an extremely poor elevator when the globe is ADducted 45 degrees from the primary position.

Right exotropia

If a right exotropia is present and the right inferior rectus paretic, however, any right hypertropia due to the partially unopposed right superior rectus would be quite obvious because the superior rectus acts far more efficiently as an elevator when the globe is ABducted (as it would be in exotropia) than when it is in the primary position.

It is obvious that vertical deviations resulting from involvement of the vertical rectus muscles are decreased (hidden) in esotropia and increased (exaggerated) in exotropia.

Discussion

A patient with 45 degrees of right esotropia and a paretic right superior oblique would have a right hypertropia due to the partially unopposed action of the right inferior oblique and the right hypertropia would be quite obvious. It would be obvious because the obliques are far better elevators or depressors in positions of ADduction than in the primary position.

If, on the other hand, a patient had 45 degrees of right exotropia and a paretic right superior oblique, although the right inferior oblique would be acting partially unopposed, its mechanical advantage as an elevator would be so poor in the position of the globe in ABduction that little or no right hypertropia would be apparent *until the eye was returned to the primary position.*

It should also be obvious that vertical deviations resulting from involvement of the obliques are decreased (hidden) in exotropia and increased (exaggerated) in esotropia.

Predictions about postoperative hypertropia

An appreciation of the foregoing facts enables one to make some perfectly logical predictions about so-called postoperative hypertropia:

1. If a *vertical rectus* is involved and there is *esotropia,* surgical correction of the esotropia will uncover or will apparently exaggerate any existing vertical deviation.

2. If a *vertical rectus* is involved and there is *exotropia,* surgical correction of the exotropia will cause any vertical deviation present to decrease or appear to disappear entirely.

3. If an *oblique* muscle is involved and there is *esotropia,* surgical correction of the esotropia will cause any vertical deviation present to decrease or perhaps make it seem to disappear entirely.

4. If an *oblique* muscle is involved and there is *exotropia,* surgical correction of the exotropia will either uncover a vertical deviation or will apparently exaggerate any existing vertical deviation.

It must be emphasized that these rules apply only to cases of lateral heterotropia in which there is but a single vertically acting muscle involved. It will perhaps have been noted that the term "involvement" rather than "paresis" or "spasm" of muscles has been carefully used, and there is a reason for this seeming ambiguity. According to Hering's law, any impulses of central origin destined for the muscles of one eye will arrive at the muscles of both eyes in equal amount. This simply means that the fixing eye will determine the innervations going to both eyes.

If the fixing eye is the eye with the paretic vertically acting muscle (whether it be an oblique or one of the vertical rectus muscles), then the yoke muscle of the paretic muscle will produce the vertical deviation. The yoke muscle of the paretic muscle is the muscle "involved" in producing the deviation.

If the nonfixing eye is the eye with the paretic vertically acting muscle, then it will be the direct antagonist of the paretic muscle which is the muscle "involved" in producing the vertical deviation. It should now be clear why the term "involved" muscle is used advisedly.

The appearance or disappearance of a vertical deviation following the surgical correction of a lateral heterotropia is neither mysterious nor should it be surprising. Accurate identification of paretic vertically acting muscles will allow accurate predictions with respect to the postoperative behavior of vertical deviations.

A careful preoperative study will enable one to diagnose paresis of vertically acting muscles as well as to identify the muscle, or muscles, involved. The subject of the diagnosis of paresis of the oculorotary muscles is beyond the scope of this paper. Suffice it to say that the laws of Sherrington and of Hering are the keys to the problem in its entirety.

Conclusion

In conclusion, it may be said that unless it was the specific intent of the surgeon, there is no such thing as postoperative hypertropia; it is really preoperative and requires only careful diagnostic study for its recognition.

SOME METHODS OF LID REPAIR AND RECONSTRUCTION

VI. Reformation of the inferior fornix

Sidney A. Fox, M.D.
New York

The inferior fornix of the anophthalmic socket is of far greater importance than the superior in the satisfactory fitting of a prosthesis. The upper fornix need only be of sufficient depth to prevent the artificial eye from slipping out from under the upper lid.

The lower fornix, however, not only does most of the weight bearing but it must also be deep enough to supply firm anchorage for the prosthesis in the usual upright position of the head. This is why, in socket reconstruction, the dissection is carried well below the lower orbital rim to provide a sufficiently deep lower gutter.

When the socket has been badly traumatized, enucleation should be done carefully and the tears in Tenon's capsule repaired meticulously. Otherwise, there may be a tendency for the orbital contents to prolapse forward with a shallowing or obliteration of the lower fornix to the point where retention of a prosthesis becomes impossible.

Figure 1A illustrates the extreme of such a case. This is not postoperative chemosis but an irreducible prolapse of orbital contents present three months after enucleation.

Figure 3A is the type much more commonly seen. The prolapse of orbital contents here has simply obliterated the lower fornix, converting it into a downward sloping shelf which pushes the lower lid outward and makes retention of a prosthesis impossible Repair of this deformity is not too complicated.

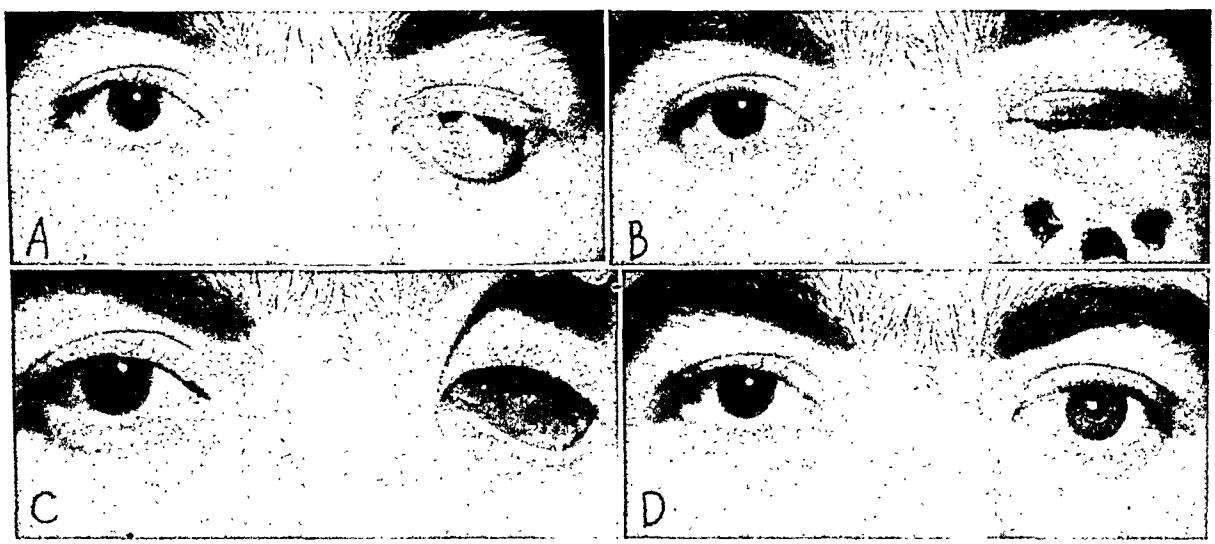

Fig. 1 (Fox). (A) Prolapse of orbital contents with obliteration of inferior cul-de-sac following trauma to globe and enucleation three months previously. (B) One week after repair, before removal of sutures. (C) Restored inferior cul-de-sac. (D) Prosthesis in place.

Technique

The conjunctiva is incised horizontally from external to internal canthus well above midline (fig. 2A, broken line) and undermined to the upper and lower lid edges. The lower conjunctiva is retracted forward and all excess fibrous tissue resected. The sub-

conjunctiva is then carefully resutured with 4-0 chromic catgut, interrupted sutures.

The inferior fornix is recreated by blunt dissection carried down to the periosteum well below the orbital rim as is done for socket reconstruction. The conjunctival incision is closed with a 4-0 black silk, running suture. Three double-armed 3-0 black silk sutures spaced equidistantly (fig. 2B) are then passed from within outward through the floor of the newly created cul-de-sac. The needles are carried close to the periosteum well below the lower orbital rim and brought out on the cheek where they are tied over oiled silk pegs (figs. 1B, 2B, and 3B).

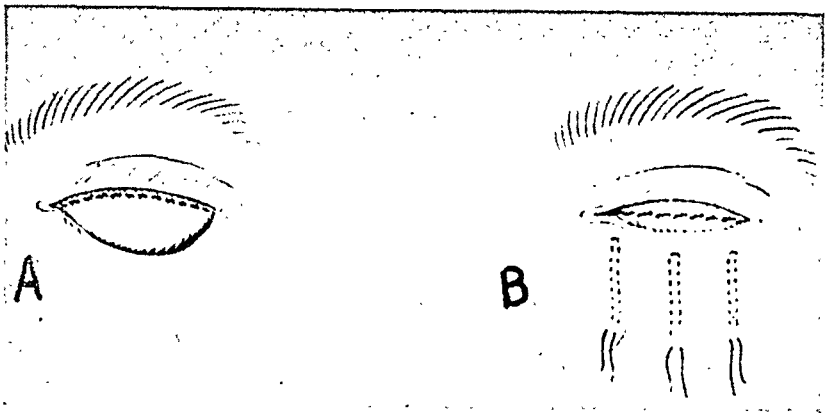

Fig. 2 (Fox). Technique of repair. (A) Dotted line shows position of initial conjunctival incision. (B) Position of sutures before insertion of conformer and application of pressure bandage.

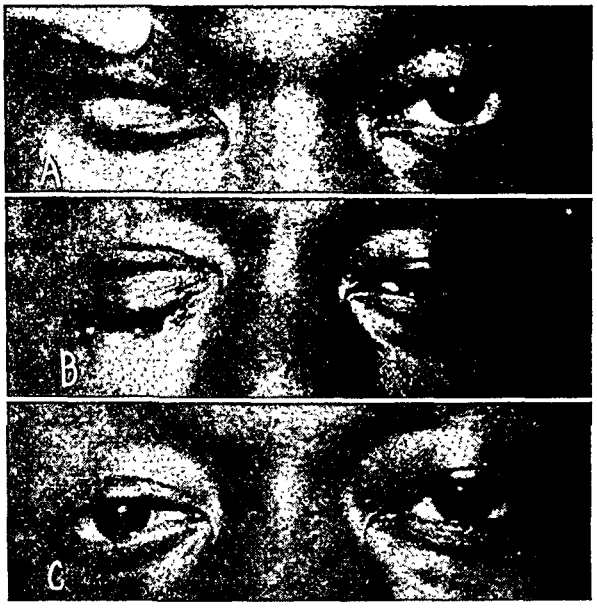

Fig. 3 (Fox). (A) Prolapse of right orbital contents with shelving and obliteration of lower cul-de-sac and displacement of lower lid. (B) Seven days after surgery, before removal of sutures. (C) Final result with prosthesis in place.

A snug conformer is inserted to assure healing of the tissues in proper position as described in a previous communication[1] and a firm pressure dressing is applied. On the seventh day after operation the sutures are removed, the conformer reinserted, and the eye repatched daily thereafter until all reaction has subsided. A permanent prosthesis may be inserted any time after the second week.

Conclusion

The problem of repair here is not difficult. No conjunctiva need be grafted since none has been lost. It is simply a matter of reconstructing the inferior fornix by a reshuffling of the orbital contents and assuring that they heal in proper position. The technique described above has been used in seven cases to good effect and is recommended unhesitatingly.

A POSTVACCINIAL OCULAR SYNDROME

EMANUEL ROSEN, M.D.
Newark, New Jersey

Ocular complications following vaccination are by no means as rare as our textbooks indicate for reports of postvaccinial ocular complications are extremely meager. The importance of the appearance of symptoms within a very constant incubation period has not been stressed. In neurologic reports, the appearance of signs or symptoms 9 to 11 days after vaccination has been shown to be pathognomonic of postvaccinial neurologic disease (Putnam,[21] Ferraro,[5] Flexner,[7] and Finley[6]). The eye should not be exempt from this response especially since it has been shown that the pathologic lesion in the brain in postvaccinial encephalitis is specifically a vascular one, possibly of allergic nature.

The frequency of unexplained exudative choroiditis in young and apparently healthy adult soldiers during the recent war is one of the outstanding impressions left upon me, as well as upon several colleagues with whom this observation was discussed. The idea of a possible relationship of exudative choroiditis and other complications to vaccination for smallpox, accidentally thrust upon me, has gradually evolved into a concept now grown to complete acceptance.

This concept aims to establish the causal relationship of any ocular eye lesion to vaccination if the incubation period is of 10 to 12 days, no matter what the nature of the lesion may be.

In order to substantiate such a diversified and far-reaching claim it was necessary not only to review the available literature upon ocular complications following vaccination, but also to obtain all available data upon postvaccinial complications, particularly of the neurologic variety.

In the spring of 1947, an excellent clinical opportunity presented itself when mass vaccination for smallpox became necessary in the New York metropolitan area. During this period I encountered approximately 50 ocular complications following vaccination, some of which I shall attempt briefly to describe.

REVIEW OF LITERATURE

Ophthalmic literature contains two varieties of ocular complications following vaccination.

A. DIRECT, PRIMARY INOCULATION

The more commonly described and better understood variety is that of direct inoculation, with pustule formation upon the lid and the production of a primary disciform corneal lesion. Of this variety there are several hundred reported cases. They are direct and primary.

Usually the individual inoculates his or her own lid or cornea by scratching the vaccination. The virus is transplanted upon the lid or upon the cornea and within 10 days a palpebral and/or an ocular lesion develops.

This ocular complication has frequently been described and is well understood. For example, Schirmer[17] first reported postvaccinial disciform keratitis in 1891 and again in 1904, at which time he reviewed 6 previously reported cases and added a 7th case.

Characteristic findings in this syndrome, according to Schirmer were:

1. A central, parenchymatous, gray, disciform corneal lesion
2. A deep, circular, grayish line resembling a ring
3. Involvement of Descemet's membrane
4. Mild uveal involvement
5. Clear peripheral cornea
6. Long duration
7. Permanent opacification

Schirmer noted the striking similarity between "keratitis postvaccinolosa" and

disciform keratitis as described by Fuchs. Schirmer tried to show that these two conditions were identical. In the cases reviewed by him the keratitis was exogenous, being produced by some form of primary contact.

B. Indirect, delayed ocular complications

The second type of ocular complication is a systemic, secondary, delayed reaction usually associated with and considered part of a postvaccinial encephalitic complication.

Ocular symptoms which appear with any of the acute exanthemas (virus) are probably of similar etiology, since the histopathologic picture of all the postexanthematous encephalitides are identical. The rarely acquired pathologic material obtained from eye sections in these diseases tend to bear out this statement (Von Herrenschwand;[19] Scheyling[16]).

There have been only a few cases recorded in which postvaccinial encephalitis has been followed by complications involving the ocular structures. Scheyling[16] reported upon a case of bilateral optic neuritis in a child, aged 14 months, with complete loss of vision appearing 2 weeks after vaccination for smallpox and associated with postvaccinial encephalitis.

The cerebrospinal fluid was under increased pressure; there was a 363 cell count; the fluid was sterile. At the onset there was marked edema of both the optic nerve and retina. Vision returned to normal after several weeks.

Scheyling believed that the vaccine virus activated a latent infection. The fact that the patient improved with convalescent serum led Scheyling to believe in the toxic or infectious nature of the disease rather than in any allergic phenomenon.

Smiley,[18] in 1903, reported a case of bilateral paralysis of all of the extraocular muscles with involvement of accommodation. These complications appeared 10 days after vaccination and were associated with other evidences of encephalitis. Complete recovery ensued after 5 weeks.

Von Pollnow,[20] in 1910, reported a case of bilateral papilledema coming on 3 weeks after encephalitis which appeared 3 days after vaccination. This 12-year-old child was left with a bilateral optic atrophy.

Giorgi[9] reported a case of bilateral optic atrophy 14 days after postvaccinial encephalitis which appeared 5 days after vaccination. The 3-year-old girl remained blind.

Von Herrenschwand,[19] in 1939, reported 3 additional cases of ocular complications in postvaccinial encephalitis. His original case, reported in 1912, was that of a 6-year-old child who developed a postvaccinial bilateral sixth-nerve palsy. Rapid improvement took place in this case. In his second report he listed 3 new cases each of which came to autopsy. The patients were approximately 8 years of age in each instance. Encephalitis occurred 7 to 10 days after inoculation with death following in 2 or 3 weeks.

Clinical eye studies were not recorded in these cases but autopsies, including sections of the eye, were performed with some rather interesting revelations. In the first case there was an internal and external hydrocephalus with recent hemorrhage below the dura upon each side of skull. Both trigeminal nerves and their sheaths were edematous. The entire histologic picture was that of an allergic response. A bilateral perineuritis of the optic nerve was present.

The postmortem examination of the second case was most interesting as regards the ocular findings. The histopathologic picture uncovered in this case was that of an early retrobulbar neuritis, a condition which rarely comes to autopsy unless death ensues from some other cause.

Von Herrenschwand believed that the presence of continuous circular lines of connective tissue within the vein was characteristic of postvaccinial neuritis and from this feature one could rule out other forms of encephalitis.

Perhaps this concept of retrobulbar neuritis as determined by Von Herrenschwand's histopathologic investigation in cases of postvaccinial encephalitis and the sugges-

tion that we are dealing with an early allergic response may fit into the picture portrayed by Benedict[2] in his studies of retrobulbar neuritis. Certainly there is more than casual coincidence in the fact that retrobulbar neuritis terminates as multiple sclerosis (Benedict[2]) and that multiple sclerosis resembles the postvaccinial encephalitis histopathologically (Putnam[21]).

Benedict's work seems further to be substantiated by Adler[1] in whose series of 100 cases diagnosed as acute encephalitis of all varieties, 15 percent eventually were recognized as multiple sclerosis because of the recurrence of attacks. Putnam has stated that certain types of encephalomyelitis represent the acute stage of a process which we know in its chronic relapsing stage as multiple sclerosis.

Parker Heath,[10] in reporting upon a case of measles encephalitis, described an ophthalmoscopic picture resembling embolism of the central retinal artery. Because of the importance of this case I am repeating the report in detail.

Report of Heath's case

Clinical history. J. P., a boy of Italian parentage, aged 6 years, was brought to Harper Hospital, April 9, 1930. The following history was obtained from the parents and the child's physician. The family history was not important other than that there had been exposure to measles. The patient was a first child, normally born after an uncomplicated pregnancy. The child had been breast fed and there had not been any serious sickness before the present attack. He had been an average child in all respects with good general health.

Present illness. Measles had begun 11 days prior to admission with the typical onset. There had been a rash and later convalescence. The temperature had not been high and on the 11th day he had arisen alert, happy, and able to see. At noon, without complaint, it was noted that he groped about in a confused manner. He also appeared indifferent to his surroundings. The father established to his own satisfaction that the boy was blind. He was sent to the Hospital and was seen the same afternoon, the 11th day following his initial measles attack.

Eye examination. The eyes were noted to have a somewhat irregular motion, attracted toward sounds, not influenced by light. There was some dissociation of the eye movements. Pupils were unequal and were varyingly dilated from two thirds to nearly maximum. The dilation varied in each eye in a period of several hours. There was no exophthalmos, bruit, nor increase of intraocular pressure. On command the child could move his eyes about in all directions. There was no swelling of the lids. The conjunctivas were clear and not congested. There was no evidence of discharge.

Ophthalmoscopic examination showed: R.E., clear media, nervehead slightly elliptical vertically, a distinct pallor of the nervehead, and a distinct loss of capillary color, without loss of substance. A thin, hazy edema blurred fine details in the physiologic depression of the nervehead. The lamina cribrosa was not seen. Both pigment and scleral rings were partially obscured. The most extraordinary picture was seen in the arteries which were reduced, practically throughout the fundus, to threads and apparently were carrying little, if any, blood. The veins were dark in color and were reduced in caliber throughout but, relative to the arteries, were engorged. No pulsation was seen. No marked increase of opaqueness was seen along the course of the vessels. The entire retina showed definite loss of transparency not associated with hemorrhage or exudation. In the macular area the foveal reflex appeared a deep red, somewhat diffuse, through a more exaggerated overlying nontransparent retina. The left eye presented essentially the same picture. In both eyes appearances closely resembled bilateral embolism of the central arteries.

Ophthalmoscopic examinations were made at intervals several times a day and showed but little change during the first week. At the end of a week there was some persistent increase in the diameter of the arteries. The retina by this time was more opaque and seemed more edematous. Blood vessels were more obscured as though suspended in a less transparent or translucent medium.

Treatment. On the 7th day the patient's eyes responded to light stimuli for a short interval. There was no increase in the caliber of the retinal arteries following inhalation of amyl nitrite. Heavy sweating from heating with an electric blanket produced slight temporary enlargement of the caliber of some of the arteries. The same phenomenon was observed following foreign-protein injections, typhoid vaccine given intravenously in sufficient amounts to cause a temperature of 103°F. Considerable apprehension was felt that the long-continued anemia would cause neuritis and permanent loss of sight.

Course. At the end of the first week in the Hospital, it was noted that, on the nervehead of the left eye, there were two small capillary hemorrhages and in the macular region were short lines and diffuse dots arranged in a regular manner, neither radiating from nor tangential to the macula. These lines did not coalesce and increased in width. In the periphery were noted similar lines which looked like short, fuzzy, wool yarns of lighter gray color than the surrounding nontransparent retina.

On the 10th day, the child suddenly announced that he could see. Tests with objects bore this out. The fundi showed more filling of the arteries.

From this time on there were irregular but steady increases in diameter of the arteries until on the 23rd day, when he was discharged, they were nearly

normal in caliber. The nerveheads still appeared pale. (This persisted for many months.) With restoration of vision and increase in the diameter of the arteries, the edema in the retina or loss of transparency disappeared.

At the end of 6 months it was noted that the arteries and veins were nearly normal in caliber and the retinas were transparent. Exceptions consisted of fine pigment somewhat lineally arranged in the macula and irregularly disposed, and definite, fine, pigment tracery throughout the extreme periphery as viewed with the ophthalmoscope.

Unfortunately, it was not practicable to make visual-field studies because of the patient's inability to coöperate. On March 16, 1931, the child's vision was 6/7, uncorrected, in each eye, and with a minor correction for astigmatism and far-sightedness it was improved to 6/6.

Comment

Since the pathology of measles and post-vaccinial encephalitis have been shown to be identical, it may be assumed that the histopathologic picture, found in Von Herrenschwand's second case, could possibly produce a variation of the fundus picture seen in Heath's case. Heath's patient revealed an eye condition which was bilateral, edematous, transitory, reversible, and, in several other features, characteristic and unquestionably allergic. The fundus picture may have been modified by the pressure exerted by fluid in the tissue spaces. The arterial thinning was related to this extra-arterial pressure; whereas, the intra-arterial pressure likewise was unusually low, for the systemic diastolic blood pressure was reported as 40 mm. Hg, or even lower.

Heath, who stated, "it is very unlikely that an opportunity will ever arise for an anatomical study of a similar case," probably would be very interested in the post-mortem report of Von Herrenschwand's Case 2. Although Heath does not claim an allergic basis for his case, it would appear that, in stressing the localized edema as the dominant symptom, he points toward just such a concept.

Furthermore, it would appear that the acute retinal edema and other vascular changes in the retina in Heath's case and the retrobulbar picture in Von Herrenschwand's case may be similar in nature to the acute perivascular pathology of encephalitis if we make proper anatomic allowances.

In 1935, Redslob[12] reported a case of spasm of the central retinal artery (bilateral), which appeared suddenly one day after vaccination in a 14-month-old child. The child was blind for 6 weeks. The eyegrounds were described as being "ischemic."

In *Ophthalmologica,* 1947, Redslob reported a follow up of this case. He stated that with vasodilators and arsenical therapy the child regained normal vision after 3 months. He noted that, although normal vision returned, the nerveheads remained pale, the arteries appeared contracted, and there was a general pallor of the fundus which caused him to suspect that the choroidal vessels might have been involved originally.

After the war Redslob met the mother of the patient, now aged 12 years, and he was told that the child had difficulty seeing at night. When examined in March, 1946, the patient was found to have a typical pigmentary retinal degeneration with tubular fields. (Redslob reported this case under a group of pigmentary retinal degenerations in which he listed the many causes of this degeneration.)

In this article Redslob referred to a case reported by Franceschetti,[8] whose patient developed an optic neuritis 10 days after vaccination. Later a typical pigmentary retinal degeneration appeared. Redslob believes that vaccination precipitates the vascular spasm which in turn produces the pigmentary retinal degeneration. (He ruled out all hereditary factors.)

A case reported by Hoffman[11] is of unusual interest in that a condition of retinal venous thrombosis following reaction to vaccine was described. The 21-year-old soldier was given stimulating injections of typhus and triple typhoid and at the same time was vaccinated with the vaccinia virus, the test being recorded as "immune." This patient

had had previous inoculations but in no instance was there any reaction to any of the injections. The past history was reported as being negative.

Two days after the inoculations the left eye became involved, the vitreous appearing turbid. A periphlebitis and venous thrombosis subsequently ensued. Sheathings, hemorrhage, and exudate developed in rapid succession. The author described this process as an acute endophlebitis followed by thrombosis. Later, optic neuritis and papillary edema developed.

Hoffman summarized this case "as an uncommon occurrence of retinal periphlebitis and progressive thrombosis in a young adult following stimulating doses of vaccines with associated anaphylactoid reaction." He noted areas of periphlebitis at the venous bifurcations and at arteriovenous crossings.

These findings throw some light upon the nature of the postvaccinial process and its circulatory disturbances. Hoffman also mentioned sheathing of the vessels which corresponds to the perivascular cerebral disturbance and may be remotely related to Rucker's[14] sheathing in multiple sclerosis. The therapeutic use of intravenous histamine as advocated by Horton would seem to be applicable to this condition.

Duke-Elder[4] mentioned a case of metastatic ophthalmia following vaccination and progressing to enucleation. This case was reported by Saltini[15] in 1894. Duke-Elder also states that in the prevaccination days, iritis and choroiditis was not an uncommon complication of smallpox, occurring in approximately 15 percent of the cases. The type of uveitis was mild in character and usually appeared upon the 8th to 12th day. These attacks may leave characteristic postvariolar atrophic areas in the iris frequently misdiagnosed as vitiligo.

Case reports

The following case reports may be grouped under these headings:

Group A ——— Keratitis
Group B — — — Chorioretinitis
Group C — · — Central serous retinopathy
Group D — — — Thrombophlebitis and thromboses
Group E — — — Panophthalmitis
Group F ——— Isolated muscle palsies

Group A—Keratitis

Case 1

History. The patient, aged 30 years, had served in the Armed Forces for slightly over four years. The onset of the acute episode of his illness occurred on March 13, 1945, one hour after the noonday meal which consisted of pork, vegetables, bread, butter, coffee, and canned fruit. The initial symptom was nausea which was followed shortly by wretching and then by vomiting of projectile character.

After the vomiting had ceased, the patient noticed a persistent, dull nuchal headache which, although it remained unchanged, did not keep him from work during the afternoon. There was no chill, dizziness, or fever at this time.

The patient slept well that night but, upon awakening the next morning, he was aware of a severe dizziness that made the bed seem to turn about in circles. In a few hours this improved so that he was able to report to work at the usual time.

Again, following the noonday meal which was eaten sparingly, the symptoms of the previous day recurred together with an oppressive tightness about the neck and the earlier acute dizziness. The patient returned to his house where he spent a quiet and comfortable night. On this second day there was no recurrence of the headache.

Upon arising on March 15th the patient was still acutely dizzy and somewhat faint. He was admitted via ambulance to the hospital where, except for mild retching, the only obvious symptom for the first week was a persistence of the dizziness, more pronounced when the patient was erect. At no time was the temperature abnormal.

Past history. The patient had had several virus diseases—mumps, measles, scarlet fever, and chicken pox—all without any serious sequelae. He had had several mild attacks of herpes labialis. He had never been hospitalized and had never been ill for longer than 3 days. He had a mild sinusitis and, during the past three months, had had frequent colds.

No history of sensitivity to plants or to sera was forthcoming. The patient had had many "shots" during his military career but none had been followed by any disturbing symptoms; in fact he seemed to suffer less locally following an injection than any of his companions. On March 6th the patient was vaccinated with vaccinia virus and given a stimulating dose of triple typhoid. There was no systemic or local reaction to the vaccination or the typhoid injection and the incident had been forgotten completely.

Physical examination. Upon admission the physical examination was reported as being absolutely

negative. The temperature was 98°F.; blood pressure, 114/86 mm. Hg.; pulse rate, 86. There were no positive neurologic signs and no physical findings other than the acute vertigo. The urine examination was negative.

A blood count showed a leukocytic count of 11,700 of which 72 percent were polymorphs and 28 percent were lymphocytes. Several subsequent blood counts showed an 8,000 to 15,000 leukocytic variance and maintenance of the first-reported percentage for the differential count.

Routine tests for syphilis, undulant fever, and tularemia were reported as negative. No spinal fluid studies were made until 10 days after the onset of the illness at which time the report was: Pressure, normal; cell count, 0; colloidal gold curve, 0....0; globulin, no increase; total protein, 22 mm.; Wassermann, negative.

X-ray studies. X-ray studies of the skull and the chest were reported as negative. Because of the persistence of the vertigo without associated symptoms otologic and neuropsychiatric consultation was sought.

Neurologic examination. The neuropsychiatric consultation is included in its entirety because it presents many interesting sidelights. This examination was performed and recorded one week after admission.

"The neurologic examination is entirely negative. There is no nystagmus or ataxia. There are no abnormal reflexes. The cranial nerves are normal. The fundi are normal. The history and physical findings do not speak for an expanding intracranial lesion.

"This 30-year-old patient has been married about four years. No children have been born. He is a lawyer by formal training and has been a member of the bar in his home state for several years. Following his induction into the army in February, 1941, he took basic training and upon its completion was assigned by reason of his previous training to a legal type of work in division headquarters.

"After several months at this type of work he applied for officers candidate school from which he was eliminated after 11 weeks because of 'lack of leadership in combat.' He was given the opportunity of remaining as an enlisted man at the same camp headquarters where he continued to work in several capacities requiring legal training and eventually he was given his present rank as warrant officer.

"Upon returning from officially granted leave on February 25, 1945, he learned that he had been relieved of his assignment and had been placed upon an available list expecting orders for duty elsewhere, possibly an overseas assignment.

"For the past three months he had been feeling generally weak, tired, and exhausted. He had always been a passive individual. He maintains a definite feeling of inadequacy because there have been no children in the marriage. His legal ambitions are of a passive type and he admits that he never pictured himself as a successful 'trial' lawyer. While at officers candidate school, he found the physical program quite difficult to carry through and upon many occasions he was forced to 'fall out.'

"This officer appears to be a passive neurasthenic individual. In the service he failed to gain a commission because of lack of physical performance and leadership of men in a combat type of duty. He was given a form of work following this failure which was technically and psychologically very acceptable to him. As a result of his work he gained a warrant officer's status which to him was very gratifying.

"While on leave, he was, without previously being informed, relieved of his command and placed upon an available list. He took this in a normal manner consciously, and reacted with, 'Well a soldier is never put.'

"Psychologically, however, this was a serious failure upon his part. With this news there was the threat of combat theatre duty and separation from his wife upon whom he depended a great deal emotionally. He reacted to the situation in the only manner he is capable of, namely, an acute episode of hysteria. His neurasthenic features have existed for many years and manifested themselves early in his military career.

"Diagnosis: Psychoneurosis and Neurasthenia."

Ear, nose, and throat consultations and studies were of indeterminate value. Upon rechecking the patient's history, it was learned that two years earlier the patient had had an episode of buzzing in his ears following diving. This buzzing had lasted only two days. As far as the patient could tell, this condition had entirely disappeared.

One week after the onset of the acute vertigo, the patient complained of auditory disturbances of transient character. He described these as two distinct entities; one was of the "cockleshell variety," the other resembled the hum of an "undialed telephone."

The otologist reported the results of his audiometric and labyrinthine studies as being unreliable, transitory, indeterminate, and contrary to expectation.

"Three separate cold water tests were performed in the first two weeks and in each the patient did not respond normally. Using cutaneous douching for two minutes failed to bring on any of the normal signs of an active labyrinth such as nystagmus, nausea, vomiting, vertigo, or past pointing."

The deafness from the appearance of the audiogram was regarded as a mixed type of nerve deafness rather than plain nerve deafness.

Ocular manifestations appeared about the first of April and were quite mild at the onset. The right eye was involved first. There was no pain and no secretion. There was a mild conjunctival injection and a very slight sensitivity to light.

Following the instillation of a mild astringent (¼-percent zinc sulfate) the eye seemed to improve and remained comfortable for about 10 days at which time there was a recurrence of similar but more severe symptoms.

Eye examination. Examination at this time disclosed a very mild aqueous flare, some increased thickening of the cornea with several folds in Descemet's membrane, and many "craters" visible in the zone of specular reflection. There were also several small foci of increased corneal opacification located in the stroma.

At various places the limbal vessels were beginning to push into the corneal substance superficially. Under atropine locally and typhoid therapy intravenously (a series of 7 injections was given), the right eye gradually cleared up after three weeks but, by this time, a similar picture was developing in the left eye.

Attacks continued to shift from one eye to the other. Each attack lasted about one week and cleared completely, leaving no sequelae. The ocular attacks appeared unrelated to any other systemic manifestation.

During one phase, sulfathiazole was used systemically without any apparent benefit other than to inform the department that the patient was sensitive to that drug. Penicillin therapy was also instituted, with the same unencouraging response.

Course. Throughout the course of the ocular illness, familiarity with the events leading up to the patient's hospitalization, the neuropsychiatric report, and the absence of conjunctival secretion even when a definite keratitis existed made it difficult to keep from suspecting a form of malingering.

CASE 2

History. J. S., a 30-year-old accountant, recently discharged from the U. S. Marine Corps, was vaccinated for the third time on April 20, 1947. While in service, he had never suffered any local or systemic reaction following any of the "shots." Just before vaccination, his physical condition had been reported as excellent. There was no unusual reaction to the present vaccination; no sense of discomfort, fever, malaise, or fatigue.

Nine days after vacination, while the patient was watching a ball game, he noted a sudden severe sharp pain in the right eye. The pain and discomfort were sufficiently intense to cause the patient to leave the game.

The next morning he consulted an ophthalmologist who removed a foreign body from his right cornea. He was told that he would be well in a day or two. The patient emphatically stated that there was no slitlamp examination. The eye appeared to improve for 24 hours but symptoms recurred after 48 hours and seemed to be much more intense than at the onset.

Ocular examination. Upon initial examination, 15 days after vaccination, I noted a mild photophobia, some epiphora, and a faint ciliary injection of the right eye.

A girdle of small gray, round infiltrates encircled the cornea. These were located about 1 mm. within the limbus and numbered 14 lesions. Each lesion was approximately 0.5 mm. in diameter and oval in shape. They were located in the anterior third of the cornea and did not stain with fluorescein. The lesions at the upper limbus appeared to be located just beyond a leash of blood vessels.

The patient was given atropine, compresses, vasodilators, and kept under close observation. In about one week the small infiltrates thinned out and became much flatter and of wider diameter. The patient was kept under observation for a period of 6 months. There were some exacerbations and some moments of marked discomfort, but the overall picture was one of gradual improvement.

CASE 3

History. Mr. J. K., aged 37 years, was first seen at Camp Lee, Virginia, in the autumn of 1944 because of a severe herpetic keratitis of the left eye. This was his third attack.

The lesions responded very slowly. Only after 10 weeks of hospitalization was improvement sufficiently permanent for the patient to be discharged and returned to duty.

He remained entirely free of eye symptoms until two weeks after vaccination in May, 1947, at which time the left eye became severely inflamed and very painful.

Ocular examination. Examination showed that the cornea was increased at least twofold in thickness, with a general overall grayness involving almost its entire surface. The conjunctiva was intensely reddened from the corneal margin to the periphery. There were a great many folds in Descemet's membrane.

The slitlamp beam showed a picture much like a section through a washboard. One vessel ran well into the substance of the cornea, starting at the 9-o'clock position and located in the deep corneal layers. At the onset, the activity seemed restricted to the corneal substance just beyond this new vessel. There was some disturbance in the aqueous. During the acute period the iris could not be seen.

Within the substance of the cornea there were several small infiltrates which were spindle-shaped in cross-section. Photophobia and lacrimation were intense. The red reflex of the fundus could not be obtained at this stage.

GROUP B—CHORIORETINITIS

CASE 4

History. Miss P., aged 23 years, was vaccinated on May 18th. On May 30th, she noticed several large opacities before her left eye which became much more pronounced in the bright sunlight or when she looked at a white background.

At first there was only a slight blur but, within 3 days, vision was reduced to counting of fingers. The patient was hospitalized at the Newark Eye and Ear Infirmary, where all routine studies proved to be negative. This included Wassermann, urine, and Mantoux (1:1,000,000 to 1:10,000 dilution) tests, sinus studies, and X-ray studies of the chest.

Past history revealed chicken pox, measles, and whooping cough—all before the age of 5 years and all mild in character. There were no complications

following these illnesses. The patient had never had any serious diseases; this hospitalization was her first. She had never had any indications of allergic reactions, and there was no family history of allergy. She was first vaccinated at the age of one year, with a normal response.

Eye examination disclosed vision of fingers only in the left eye. The pupil was widely dilated. There were many keratic precipitates of greasy character throughout the corneal structure, fairly large and widely dispersed.

The vitreous contained many large grayish opacities, some globular in shape, others resembling large strands. These vitreous opacities were especially thick in the region of, or just anterior to, a large, yellowish gray choroiditic patch which was about 3 disc diameters in size. This exudate was quite recent with edges still not healed and still nonpigmented.

Although it was difficult to see through the turbid vitreous, particularly in this region, an old choroiditic patch could be seen just a little beyond this lesion. It was heavily pigmented and completely healed, and was located in the upper nasal field. The disc appeared normal, although it could not be seen too clearly.

CASE 5

History. Mrs. R., aged 29 years, was moderately myopic. She had had annual refractions by a well-known ophthalmologist. Vision had always been normal with glasses. Physical examination, after the birth of her second child and three months before the onset of her present eye complaint, indicated no abnormalities.

About 20 days after an uneventful revaccination, the patient complained of small spots in front of her left eye that gradually became more pronounced until, in about 3 days, vision was limited to finger counting at 4 feet.

Ocular examination. The left eye had a characteristic severe chorioretinitis with many large and small keratic precipitates, a very turbid vitreous, and a large choroiditic patch, of recent origin and extremely exudative, in the upper nasal quadrant. A small hemorrhage was present nearby. Near this new lesion were several smaller, old, pigmented choroiditic patches all crowded along the path of the same blood vessel.

Under atropine, compresses, vasodilators, and rest, no appreciable improvement was noted during the next several weeks.

The systemic investigation showed no etiologic factor. The following laboratory studies were normal: Blood count, sedimentation rate, and chemistry, urinalysis, Mantoux test (1:1000 dilution), Wassermann and Kahn test, and chest X-ray studies.

CASE 6

History. Miss F., aged 37 years, injured her right eye at the age of 5 years, with a resultant corneal scar, anterior synechia, and oval pupil. Corrected vision in this eye was 20/50.

At the age of 20 years, she developed a choroiditis involving the left macula. The history indicates that there was a positive response to the Mantoux test. Then followed a period of desensitization, and the patient remained symptom free for 15 years. Vision in the left eye was reduced to and remained at 20/200.

About three weeks after vaccination in the spring of 1947, the patient noticed an increased visual disturbance in her left eye along with many opacities seen as small round spots when looking into bright light. A few days later she was examined by an ophthalmologist who informed her that she now had evidence of a recurrent chorioretinitis involving the macular region.

Further questioning about the period following vaccination revealed that her ocular discomfort started 2 weeks after vaccination. The chorioretinitis responded slowly.

Physical and laboratory investigations failed to disclose any systemic abnormality. Examination 6 months after onset showed no activity of the macular lesion which was completely encircled by a ring of pigmentation.

CASE 7

History. When seen 10 days after typhoid and vaccinia inoculations, the patient said that blurred vision had appeared 7 days after the inoculations. He presented an acute choroiditis with evidence of several older choroiditic patches along the same vessel. He had had several previous vaccinations while in the army but had never been aware of any discomfort, systemic or ocular, following vaccination. The medical "work up" revealed no systemic abnormality. The acute choroiditis gradually healed and after several weeks became completely pigmented.

GROUP C—CENTRAL SEROUS RETINOPATHY

CASE 8

History. Mr. M. C., a 38-year-old radio mechanic, considered himself to be in good health. He had had no physical ailments for several years. There was no history of allergy, either immediate or remote, no history of vasoneurosis, nervous tension, or other features associated with vasospasm. The patient did not smoke.

Upon awakening 3 days after being vaccinated, the patient observed a spot in front of his left eye, most noticeable when he gazed at a white background.

Examination revealed a characteristic central serous retinitis. Physical examination, including blood-pressure studies, was normal. The lesion cleared completely in 3 weeks. There was a characteristic central scotoma.

CASE 9

History. J. G., a jeweler, aged 38 years, developed a spot before his left eye 10 days after vaccination. Vision was only slightly impaired so

that he paid little attention to this impediment except when he attempted to use his jeweler's loupe, at which time he became aware of his inability to see the object at which he was gazing unless his fixation became eccentric.

When examined 3 weeks after vaccination, he was found to have a typical central serous retinitis which cleared in 3 weeks. This patient had a mild hypertension. He had been under observation for 12 years and had never had any previous ocular condition of this nature.

Group D—Thrombophlebitis and thromboses

Case 10

History. E. N., a 21-year-old Negro soldier, was vaccinated and given triple typhoid injections simultaneously. Blurred vision gradually appeared in the right eye until at the initial examination, 10 days after vaccination, vision was reduced to hand movements at 3 feet.

Ophthalmoscopic studies disclosed a thrombosis of the central retinal vein of typical water-spout appearance. The fundus was a striking yellowish color. At arteriovenous crossings and at venous bifurcations, there appeared to be a strange connective-tissue prominence that suggested a perivascular strangulation.

The hemorrhagic appearance progressed and, after 2 weeks, the ocular picture suggested a superimposed arterial obstruction. Secondary glaucoma developed after 6 weeks.

Case 11

History. M. H., a 24-year-old man, was apparnetly in excellent health at the time he was revaccinated against smallpox. Upon awakening 21 days after vaccination, he noted blurred vision more apparent in the right than in the left eye.

Since he was unable to continue his clerical work, he consulted an ophthalmologist who found the patient's vision to be 20/50 in the right eye and 20/40 in the left.

Ocular examination. There was a mild bilateral macular edema and the suggestion of a generalized perivascular bifurcational constriction. The eye became worse in the next 3 days. When examined on the 24th postvaccinial day, vision was 20/70 in each eye. At this time the macular edema and perivascular involvement were quite pronounced.

Under vasodilators, atropine, and rest, there was gradual disappearance of the edema and return of vision to normal. Etiologic investigation revealed nothing abnormal.

Group E—Panophthalmitis

Case 12

History. J. W., a 28-year-old soldier, was vaccinated and given triple typhoid injections 4 days after he was inducted into the army. His past history was entirely negative. There was no allergic background. There had been no previous hospitalizations and no history of any serious illnesses.

On the 7th day after inoculation, the patient's arm became markedly swollen. Chills, headache, vomiting, and a temperature of 104.6° F. developed. The patient was hospitalized on the 8th day. The temperature fell to 101° F. on the 10th day, but at this time the patient complained of pain, redness, and blurred vision in his left eye.

Ocular examination. The next day the left eye disclosed a very severe iritis characterized by a plastic gelatinous deposit in the anterior chamber. The usual therapy was ordered but, within 48 hours, the eye became much worse. The entire chamber was filled with a yellowish mass.

A paracentesis was performed. Culture of the aqueous proved to be sterile. In 5 days light perception was lost. At the end of 6 weeks, the blind eye had become quiescent.

Group F—Isolated muscle palsies

In this group several cases of isolated muscle palsies were observed, all coming on 7 to 10 days after vaccination. In all cases, the muscle disturbance disappeared completely after 3 or 4 weeks.

Conclusions

1. An attempt has been made to classify the ocular complications which may follow vaccination into two groups:
   - A. The direct, primary self-inoculation from contact with a pustule and leading to the production of a modified vaccination upon the lid or cornea.
   - B. The indirect, delayed, secondary ocular complication, arising through a vascular channel with the production of a variety of ocular lesions but following a very definite and constant incubation period.
2. An attempt has been made to show that this secondary type of lesion closely resembles the encephalitic type of postvaccinal complication in which the specific pathologic picture of perivascular myelinoclasis is likened to the vascular and perivascular ocular disturbance.
3. An effort has been made to point out that, in this postvaccinal ocular syndrome, there is no specific lesion. The lesion involves a highly vascular structure in every instance. A previously traumatized or a previously sensitized site is usually selected. However, it can be shown that it is the vascular portion of this site which partakes of the pathologic reaction.

That this may be true even in the avascular cornea is shown by the work of Rich and Follis[13] who attempted to study allergic phenomena in a vascular tissue and concluded that sensitization occurs at the capillaries of the corneal limbus and not in corneal tissue proper.

They showed that, in animals previously sensitized, serum subsequently injected into the cornea produced inflammatory changes at the limbus; however, if one eye had an artificially vascularized cornea, the serum placed into the cornea of a sensitized animal produced a hemorrhagic area within the corneal stroma itself.

There is no cardinal group of symptoms for this ocular syndrome. As in postvaccinal encephalitis, the variety of the signs and symptoms and the very definite incubation period—namely, 10 to 12 days—are the important diagnostic elements.

5. From these case reports, it is not difficult to assume that the eye may be the mirror in which allergic cerebral pathologic conditions, encountered in the postexanthematous encephalitic state may actually be visualized. Indeed, the sequence of events described in the venous thrombosis of the retina is not unlike the pathologic picture portrayed by Ferraro[5] in the studies of postvaccinal encephalitis.

In each case, there can be shown a very definite incubation period, followed by a variable shock reaction, and not infrequently including a previously injured or sensitized area. The edematous outpourings in the fundi, with perivenous infiltration, perivasculitis (sheathing) thrombus formation, endophlebitic phenomenon, neuritis, hemorrhage, and occlusion are extremely like the acute perivascular myelinoclasis in the postvaccinial encephalitic state. In mild instances, this may be reversible.

6. Since postvaccinial encephalitis is a comparatively new disease, first described 23 years ago, it is not difficult to understand the infrequency of observation of this postvaccinial ocular syndrome. Its recognition by ophthalmologists and its publication will indirectly aid in warning against indiscriminate mass vaccination not only of the vaccinia virus but also of other virus vaccines.

7. From the ophthalmic point of view, it is important to keep this syndrome in mind since the introduction of therapeutic sera may be of definite harm. The efficacy of foreign-protein therapy or the introduction of other viruses at the height of an altered blood state should be questioned.

8. An etiologic suggestion is offered for the new syndrome of "nonsyphilitic interstitial keratitis and vestibulo-auditory symptoms" as described by David Cogan.[3]

THE FOGGING METHOD OF REFRACTION*

A Comparative Analysis

James Miles O'Brien, M.D.
Bridgeport, Connecticut
AND
Robert E. Bannon, B.S.
New York

Introduction

There are many conflicting opinions[1] concerning the value and application of the fogging method of refraction. Most of those who have expressed opinions have not presented data to support their beliefs. Therefore, this report of the refractive results obtained on 500 cases examined with and without cycloplegics should contribute to the factual knowledge on refractive procedures and provide a better basis for evaluation. At the outset, it should be mentioned that the purpose of this survey has been to present and discuss the data obtained, rather than intimate that a certain technique is the final answer to all refractive problems.

Procedure

In obtaining the material for analysis, 500 cases were examined for refraction by both the fogging method and by the use of a cycloplegic. The patients were of the class who usually consult private practitioners; that is, they were not clinic patients.

Cycloplegics were used when the age, symptoms, and other characteristics indicated that some additional information might be provided relative to the patients' visual problems. Both atropine and homatropine were used depending upon the age of the subject; those under 10 years of age were given atropine and older patients were given homatropine in conjunction with paredrine. Atropine sulfate (1 percent) was used routinely in cases under 10 years of age. The drug was administered for three days, 1 drop in each eye 3 times daily and 1 additional drop in each eye on the morning of the fourth day. The patient was refracted upon the fourth day.

Homatropine hydrobromide (5 percent) combined with paredrine (1 percent) was used for the older patients. The drugs were administered at 3-minute intervals; first one drop of homatropine, then a drop of paredrine, then a second drop of homatropine. The extent of the cycloplegia was judged by the residual accommodative ability of the

* The data included in this paper were obtained from the Clinical Division of the Dartmouth Eye Institute, Hanover, New Hampshire, when the authors were staff members at that institution.

subject. The patient was refracted one hour after administering the last drop and if more than two diopters of accommodation remained, further cycloplegic was given.

With regard to the cycloplegic findings, the correction which gave the maximum visual acuity was taken as the cycloplegic result to be compared to the noncycloplegic correction. The data then, represent a direct comparison between the two methods of refraction as obtained from 1,000 eyes subjected to both types of measurement.

The findings have been studied from four main aspects as follows: (1) The changes noted in the spherical findings; (2) the changes noted in the cylindrical findings (astigmatic changes); (3) the changes as influenced by the various types of refractive errors dealt with; (4) the changes as influenced by the subject's age. Each aspect will be discussed individually.

TECHNIQUE

CYCLOPLEGIC CASES

It is pertinent at this point to outline the type of refractive technique employed in this survey. Concerning the cycloplegic cases, the refractive method differs in no essential manner from the accepted principles presently used by most clinicians. One point is worth noting, however, and that is the testing of the patient for residual accommodation following the use of a cycloplegic. An accommodative ability of greater than 1½ diopters called for further use of the drug in order properly to relax the ciliary muscle.

In judging the amount of residual accommodation present after proper time had been allowed for the action of the cycloplegia, two methods were routinely used—the near point as measured by the Prince rule, and the use of minus spheres while the patient fixated a target at a known distance.

Obviously, if the refractionist uses cycloplegics to eliminate accommodative ability in order to measure the so-called static error of refraction, it behooves him to measure the effectivity of the drug employed.[2] Otherwise the drug is being used as a mydriatic, which in itself is small cause for the use of a cycloplegic drug, that is, merely to obtain a large pupil for retinoscopic purposes.

Having been assured then, of the proper effect of the cycloplegic, the patient was retinoscoped. The working distance used was 66 cm. and minus (negative) cylinders were used throughout. The most hyperopic or least myopic meridian was neutralized first, and then by means of minus cylinders the most myopic or least hyperopic meridian was neutralized. A slight overcorrection of hyperopia, or undercorrection of myopia, was obtained in both meridians by subtracting one diopter (plus 1.0D.) from the retinoscopic findings rather than the amount required for the retinoscopic distance employed (plus 1.5D.). This allowed for at least one-half diopter more plus than required by the retinoscopic measurement and enhanced the use of the astigmatic chart and dial.[3]

Since the accommodative element had been removed sufficiently by the cycloplegia, the estimation of the astigmatic interval by means of these subjective tests was accomplished in the same manner as if the patient was fogged. Care need only be taken that one does not undercorrect the hyperopia or overcorrect the myopia present as ascertained by the retinoscopic procedure.

Having thus estimated the amount and axis of the astigmatism, the sphere which gave maximum visual acuity was then found and combined with the cylindrical measurement representing the final and basic cycloplegic measurement. It is this finding that forms the basis of the comparison herein studied.

NONCYCLOPLEGIC ESTIMATION

With regard to the routine followed in the noncycloplegic estimation, every effort was made to keep the procedure standardized, in order that the comparison could be

as free from individual error as possible. The procedure was as follows.

Initially, an attempt was made to estimate roughly the error to be dealt with, either from the patient's old correction, or from clinical findings evident upon further examination. Therefore, when beginning the retinoscopic procedure as much previous information had been obtained as possible, and a fairly proximate idea of the general type of error at hand was possible in many instances.

In retinoscoping the patient the most hyperopic meridian was again first neutralized and then the opposite meridian checked with minus cylinders.*[4] Enough spherical correction was then left in the trial frame which gave a slight against movement in both meridians when retinoscoped. This step combined with the addition of one diopter of minus rather than the 1½ diopters required for the retinoscopic distance of 66 cm. insured an adequate fogged condition at this point.

Next, the attention of the patient was directed to the astigmatic chart and dial and the astigmatism measured. The cross cylinder was used routinely in checking both the axis and strength of the required cylinder. The routine was completed by finding the required sphere and the correction thus obtained formed the basis of the comparison in this analysis.

Care must be taken by the clinician to be fully aware of the principles, both optic and physiologic, involved in the proper use of these subjective tests.[5] Should the fog be inadequate or the clinician unable to interpret the patient's responses, the procedure will become at once confusing and the results more so. Obviously, the interpretation of the phenomena as seen by the patient requires a certain degree of intelligence since the test is purely a subjective one. It is expedient then, that the patient either be old enough or have enough mental vigor to respond properly to the questions offered. In the event that these conditions cannot be properly fulfilled, objective rather than subjective measurements must be resorted to.

In estimating the degree of fog present the use of a small sphere (either a 0.25 or a 0.37 diopter sphere) is frequently a valuable aid. A minus sphere is used in conjunction with a plus sphere and these spheres are placed in rapid succession before the eye being tested. In most instances, the patient's response will indicate the degree of fog present. If by quickly placing the minus sphere over the eye we get an increase in visual acuity of say one line and conversely by placing the plus sphere over the same eye we decrease the acuity by a line, the fog is usually satisfactory.

This is important since the results obtained with the patient overfogged can be as confusing as when inadequately fogged. If the results do not follow this pattern, the sphere in the trial frame should be again checked for its accuracy.

Discussion of the data

1. Spherical changes

In Figure 1 may be seen a curve which represents the entire series plotted to show the amount and direction of the changes between the two methods. These changes are spherical changes only. Each individual circle represents a group of cases in which a change has been found. The percentage figure represents the number of cases showing a change. The abscissa depicts the amount and direction of the observed changes. The zero represents no change between the two findings. Those cases plotted to the left of the zero represent instances in which more plus or less minus was found

* It would be well at this point to mention the reasons for using minus cylinders. First, by using minus cylinders throughout both the retinoscopic and subjective portions of the examination, the duration and degree of the fog present is enhanced. Second, those changes taking place in the amount of the astigmatism present due to accommodation are kept to a minimum.[4]

with the fogging method and those plotted to the right of the zero represent the number of cases showing more plus or less minus with the cycloplegic measurement.

It will be seen at once that the apex of the curve represents about 27.5 percent of the series. This means that 27.5 percent

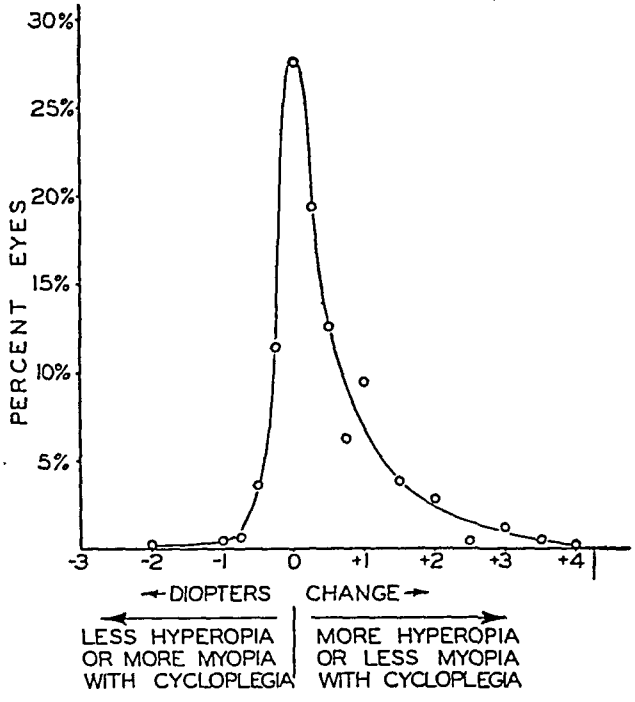

Fig. 1 (O'Brien and Bannon). Amount of spherical change found under cycloplegia. (All cases combined, 1,000 eyes.)

of the cases examined showed differences between the two methods that are not clinically measurable. In other words, the changes are less than one quarter of a diopter in either direction. However, if we take ±0.50 diopter as a comparative figure we find that almost 75 percent of the cases in the series show a similarity well within this measure.

Further study of the curve indicates that of those cases showing a difference, the majority of them lie to the right of the zero. This is the expected finding, since it would naturally be supposed that the cycloplegic cases would reveal more plus as compared to the fogging estimation.

The number of cases showing greater than 0.50 diopter of hyperopia or less myopia averages almost 24 percent. However, it is quite interesting to note the cases grouped to the left of the zero. These cases reveal less hyperopia and more minus when examined under cycloplegia. They represent 1.3 percent of the series and the changes found in this percentage were differences greater than 0.50 diopter. This phenomenon has been previously mentioned by Burdon-Cooper.[6]

2. Cylindrical changes

Figure 2. It will be noted that this curve is quite similar to the curve in Figure 1 which represents the spherical changes between the two methods of refraction. How-

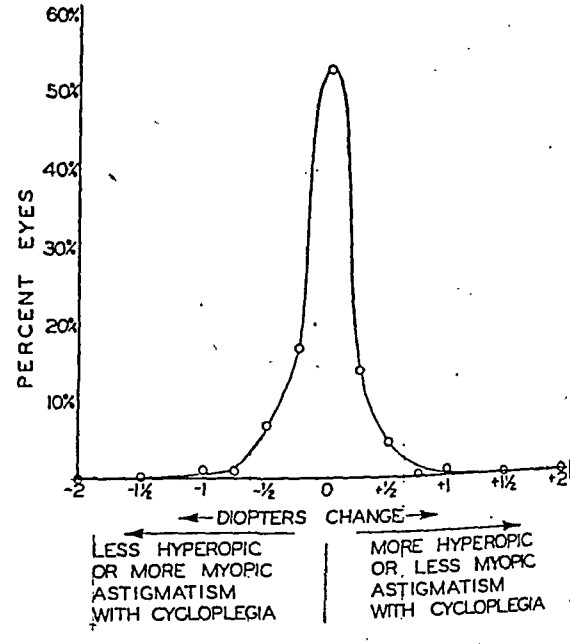

Fig. 2 (O'Brien and Bannon). Amount of cylindrical change found under cycloplegia. (All cases combined, 1,000 eyes.)

ever, inspection will further show that the changes, while following the same general pattern, are less pronounced than those in Figure 1. In this curve almost 85 percent of the cases show agreement within 0.25 diopter in either direction. If we allow 0.50 diopter in either direction as a unit of comparison, then the percentage of cases show-

ing appreciable changes in any direction become clinically negligible.

The disposition of the cases revealing difference is also interesting in that the grouping is placed evenly on either side of the zero marking, this being a slight change as compared to the curve seen in Figure 1. In plotting this curve, the most hyperopic meridian was used as the spherical component with the result that the astigmatism is represented by minus cylinders.

3. Type of error and its influence on changes found

Figure 3 illustrates the changes found between the cycloplegic and the fogging measurements as influenced by the type and degree of ametropia measured. Four sections of the graph will be noted, and, starting with the top section, the curves represent errors of increasing degree. Thus, the top section represents those cases having errors of from emmetropia to 2 diopters. In all instances, the solid line represents the hyperopic cases and the broken line the myopic cases. In this group, the myopic curve is similar to the overall curve as seen in Figure 1, but the hyperopic curve reveals more cases placed to the right of the zero. The disposition of these cases to the right of the zero represents a small number of cases actually, but the trend is as would be expected.

The next section (below) represents errors of from 2 to 4 diopters. Here both curves are flatter and show a greater spread to the right of the center. The swing of the hyperopic curve to the right is well marked, but the number of cases actually involved is small when the percentage is checked. Also the total number of cases is much smaller than the top curve.

The third section of the graph represents errors of from 4 to 6 diopters. The curves represent a total of some 75 eyes, so that the actual number of cases forming the curves is quite small compared to the top section.

The bottom section represents errors greater than 6 diopters and, as would be expected, it was in this group that the widest discrepancies occurred. Also, the total number of eyes examined was the smallest,

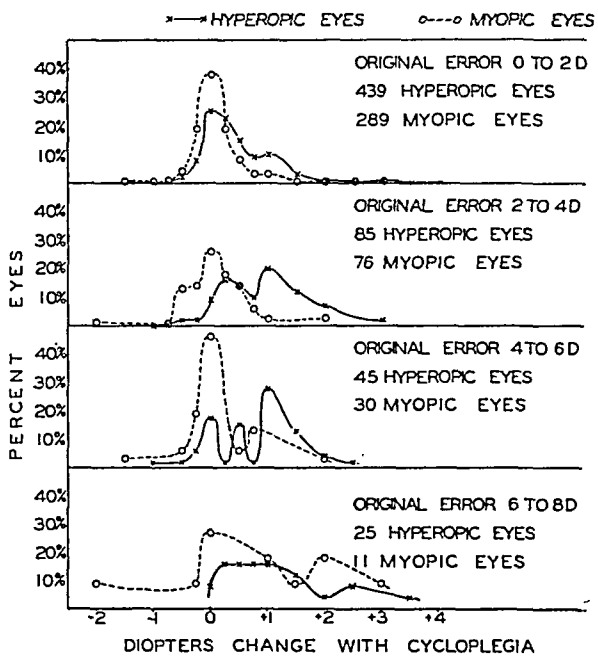

Fig. 3 (O'Brien and Bannon). Influence of original error on differences found under cycloplegia.

therefore the actual amount of change is least of all.

4. The age factor

Figure 4. Definite changes were noted when the results were considered from the age aspect. Four curves were drawn representing four standards of comparison which can be noted on Figure 4. The bottom curve depicts the changes observed when one quarter of a diopter was used as a means of comparison. The top curve represents changes of one diopter, plus or minus. The intermediate curves show changes of ½ and ¾ of a diopter. The most striking differences are immediately noted in the first column which is composed of those cases between 10 years of age and younger. It will be noted that the percentage of cases showing no change is less in this group than any

subsequent age level. Also it will be seen that after reaching the 15-year group the curve becomes almost straight. From Figure 4 the influence of the age of the subject can be clearly seen with its attendant results.

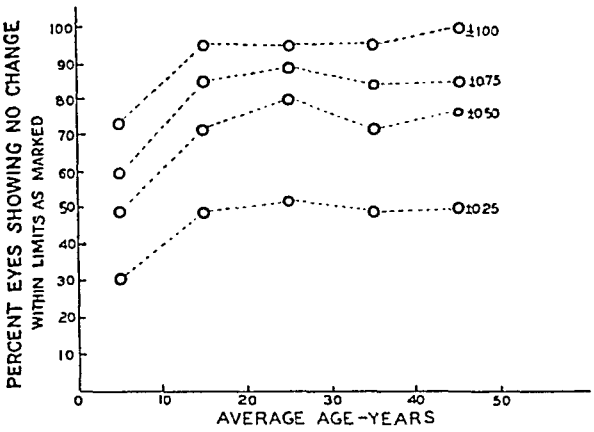

Fig. 4 (O'Brien and Bannon). Influence of age on differences found under cycloplegia using various limits of precision.

SUMMARY

The differences in spherical and cylindrical findings as found in 1,000 eyes refracted without and with cycloplegia are presented. The data may be summarized as follows:

1. In 74.4 percent of the cases, the spherical ametropic findings agreed, when ±0.50D. is allowed as being clinically insignificant and open to possibility of being due to errors of repeatability (fig. 1).

2. In 24.3 percent of the cases, more than 0.50D. greater hyperopia or less myopia was found under cycloplegia (fig. 1).

3. In 1.3 percent of the cases, more than 0.50D. greater myopia or less hyperopia was found under cycloplegia (fig. 1).

4. In 84.5 percent of the cases the cylindrical findings agreed within the clinical limits of 0.25D. (fig. 2).

Although not shown by a graph, a study[7] was made of the axis change under cycloplegia and agreement (within ±5°) was found in 81.8 percent of the cases.

5. The influence of the amount and kind of original error on the spherical difference found under cycloplegia indicated that, in general, greater differences were found in hyperopic cases and in cases having the greater degree of ametropia. Although this trend is fairly consistent, it is not particularly marked in amount (fig. 3).

6. The effect of the patients' ages on the spherical differences found under cycloplegia when various allowances (±0.25D., ±0.50D., ±0.75D., ±1.0D.) are made indicates that, in general, the greatest differences under cycloplegia were found in the younger age group—under 10 years of age (fig. 4).

Beginning with the 15-year-old group, the curve is quite flat up to the age-45 group. It shows that, when an allowance of ±0.25D. is made, the findings by both methods agreed in about 50 percent of the cases; when the allowance is ±0.50D., the findings by both methods agreed in about 75 percent of the cases; when the allowance is ±0.75D., the findings agreed in about 85 percent of the cases; and when an allowance of ±1.0D. is made, the findings agreed in about 95 percent of the cases.

CONCLUSION

The most significant fact derived from this analysis is the large percentage of agreement between the two types of refractive procedures. If one allows one-half diopter or less as a satisfactory standard of clinical agreement, then almost 75 percent of the cases surveyed show similarity within this norm. Thus, at least this percentage of an average refractive series can be said to be properly amenable to this type of noncycloplegic refraction. The influence of the age of the subject, and the type of error dealt with has been discussed and the variance pointed out. In both instances, the changes are what is estimated and expected. Even the differences in these two instances are small when compared to the overall agreement.

It is hoped then, that this study will offer

a better appreciation of the fogging of refraction and of its widespread application in refractive procedure. The capable refractionist should be familiar with the technique involved and with the limitation of its use as discussed previously. The efficacy and ease with which this technique can be employed in determining refractive errors makes it, at once, a valuable and efficient office procedure.

BINOCULAR REFRACTION*

PAUL W. MILES, M.D.
Saint Louis, Missouri

Binocular methods of refraction have been said to be superior to monocular,[1] but most of the evidence has been theoretical. The only methods that have had much clinical usage are stigmatoscopy and the Dorland Smith method of using a plus 1.5D. sph. as an occluder.

In this paper I wish to add some experimental and clinical evidence on the subject, and point out the advantages and possible errors in the method. The two parts of the discussion will be, first, whether binocular refraction induces relaxation of accommodation during the procedure and balances the accommodative tone of the two eyes, and second, whether it is desirable to determine the axis of astigmatism under binocular or monocular conditions.

Whether the refraction is with or without cycloplegic is irrelevant here. Those who use binocular refraction say cycloplegic refraction deserves the added safeguards of fogging and binocular conditions.

Dorland Smith showed that if the retinoscopic or rough subjective refraction and plus 1.5D. sph. were placed before each eye in the trial frame, the patient would gradually relax accommodation, often as much as under homatropine. Frequently, the binocular acuity would start at 6/60, but gradually improve to 6/20 or better. This, he called cyclodamia, or a method of control of the ciliary muscle tone while refracting. It is binocular technique because, throughout the procedure, one is constantly asking the patient his acuity with both eyes open and fusing. First one eye and then the other eye is covered briefly, and the acuity compared. If one eye is blurred, minus sphere is placed before it, and the acuity compared. When the acuity is equal at the binocular 6/60 level, 1.5D. sph. is removed from one eye while the cylinder is determined by the Jackson crossed cylinder. It is true that the blur level depends on the intelligence and ability of the patient to interpret blurred imagery, so the sphere removed may be more or less than 1.5D. The cylinder is measured on the other eye by transferring the plus 1.5D. fog to the first one. If any change in amount of cylinder is made, the fog is replaced before each eye, and the balance repeated. Equality of visual acuity at the 6/60 level is considered as important as at the 6/5 level. Criticism of this view will be presented.

To determine the effect of plus 1.5D. uniocular fog on fusion, one simply measures fusional amplitudes. A patient with strong dominance may suppress and never get diplopia with increasing prism with as little as plus 0.25D. or 0.5D. before the recessive eye. Most patients have mixed dominance, or only moderate dominance, however, so that suppression does not interfere with the test. If the dominance is great, the patient may be so disturbed by the blurred dominant image while the recessive eye is being tested that he cannot discriminate as well as with complete occlusion of the dominant eye.

In most patients the fusional amplitudes are little disturbed by the uniocular fog until it exceeds plus 1.5D. There is some decrease at 0.25D. and 0.5D., but no further change up to plus 2.5D. Vertical and torsion amplitudes on the synoptophore break at about the same torsion with or without fog on one eye.

The plus 1.5D. fog should be placed in the rear cell of the trial frame to get the least magnification and therefore the best fusion. Magnification of the retinal image

* From the Department of Ophthalmology and the Oscar Johnson Institute of the Washington University School of Medicine.

is about 1.5 percent in the rear cell and 3 percent in the front. For determination of the cylinder, a lesser fog may serve equally well as an occluder and permit maximum fusion. Possible rotation of one of the fused images within the other magnified image could not be more than 1.5 degrees and is not significant.

Another method of obtaining binocular refraction is to use a smoked glass before the eye not under test. This method lacks the beneficial relaxation of accommodation induced by a plus sphere, which will be discussed later. The polaroid and stigmatoscopy methods are subject to the same criticism, although they excel in patients with strong dominance.

If one eye receives a stimulation from a near object that forces it to accommodate, the other eye, even if covered, will accommodate an equal amount. This is a conditioned reflex, since under no normal situation does one eye have to accommodate more than 0.3D. than the other. One eye is never more than 3.2 cm. more distant than the other from any object fixed. In the ordinary situation of fixation at 33 cm. with the gaze roving 10 cm. in either direction, there may be 0.15D. difference in the two eyes, easily absorbed by the normal depth of focus, about 0.5D.

The accommodative level is a binocular reflex, governed by an unconscious cortical demand for the clearest possible image. Like the fine tremor of the following eye due to the fixation and fusion reflexes, there is a slow fluctuation of the level of accommodation by which the cerebral center can select the level affording the best acuity. Under the influence of plus 1.5D. fog, accommodative effort brings the image still more preretinal and blurred, whereas relaxation is rewarded by a clearer image, nearer the retina.

If the retinal images in the two eyes send conflicting reports to the cortex, there is confusion, and one report must be suppressed. This usually occurs in the more blurred eye depending on dominance. If accommodation will sharpen the image of the eye under refractive test while the other is well fogged, the impulse to accommodate gets through and both eyes accommodate. This is particularly true in determining the astigmatism, and both meridional images must be kept at the retinal or just preretinal level to prevent an accommodative stimulus.

This reflex can be demonstrated in a hypermetropic patient without cycloplegic. Place a trial frame before his eyes with both cells empty. Retinoscope with distance fixation, and gradually increase plus sphere monocularly until reversal of the reflex occurs. Now decrease plus sphere until the original "with" movement is restored. This may require removal of several diopters, whereas precision with the retinoscope is usually much better. One must conclude that the patient was induced to accommodate. Why? At first, the patient had to accommodate to see the distant target. As more and more plus sphere was added to one eye, the accommodative level was gradually lowered or relaxed until it could relax no more. The eye under test controlled the level of accommodation until the image of the distant point light became preretinal and blurred. This point appears 1.5 diopters before retinoscopic reversal. Upon blur, however, the eye suppresses, and the other eye with its image postretinal takes over fixation. Accommodation is required and, of course, the retinoscope reveals immediate reversal in the original eye. Plus sphere must be placed in both trial frame cells to prevent such accommodation.

To further demonstrate this effect of accommodation of one eye on that of the other, experiments on several individuals were performed on the haploscope (fig. 1). In this device, the subject has his head fixed in the primary position toward a Snellen chart at 15 feet. The instrument has a lateral arm on each side with a fulcrum exactly below the rotation center of each eye. Fastened anterior to the arm just before each eye is a half-silvered mirror, placed so that a target

held on the arm is seen projected straight ahead toward the Snellen chart, but only by the eye on which the arm rotates. The mirror, of course, does not prevent view of the Snellen chart. A fixed plus sphere on this arm separates the eye from the object, so that when the object is placed at a zero point on the arm, it is optically at the same distance as the Snellen chart, 15 feet. This is simply to avoid unwieldy 15 foot arms. At the zero point, this object should superimpose the Snellen chart, and be in equally sharp focus.*

Now, if the left eye sees only the Snellen chart, and the right eye sees both the fused chart and also the target on the right arm, the state of accommodation of the right eye can be determined by moving the right target back and forth on the arm, which is calibrated in diopters nearer or more distant than the Snellen chart. If a minus sphere be placed before the left eye, forcing it to accommodate, the resulting accommodation of the right eye can be measured by adjusting the target on the side arm to its sharpest

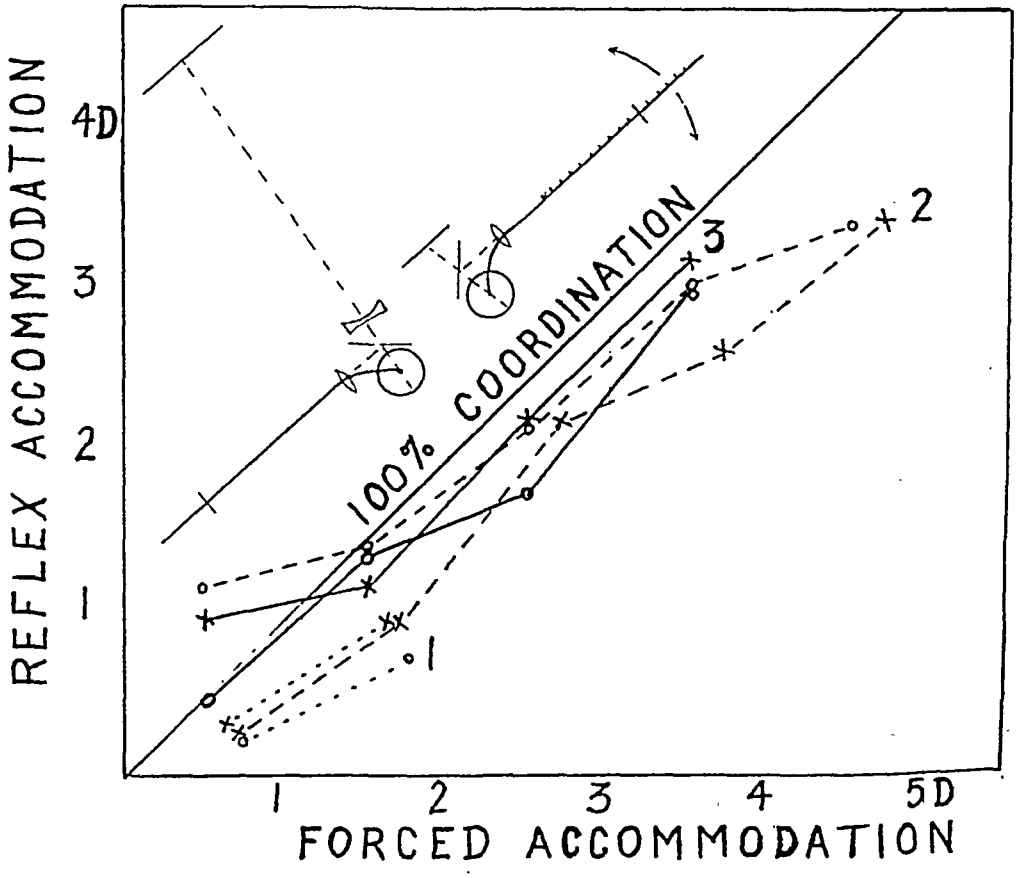

Fig. 1 (Miles). Accommodation in diopters. Forcing one eye to accommodate by minus sphere causes the other to accommodate an almost equal amount. Circles indicate right eye forced, left eye tested behind screen. Crosses indicate left eye forced, right eye tested.

*In the use of this haploscopic set up, it is unusual to find that the eyes are accommodated exactly on the Snellen chart at 15 feet. It is found upon adjusting the uniocular target on the side arm that although both eyes are fixed at 15 feet, the sharpest focus of the eye tested is nearer than 15 feet by 0.5 diopters. This may be because of the depth of focus of the human eye. If the eye is focused exactly at 15 feet, or 0.2D. it is also in focus at infinity, and at 1.4 meters, which is 0.7D. The retinal image is sharp over such a range, that an innervation to accommodate or relax accommodation is not stimulated.

focus, vision being fused on the Snellen chart.

The resulting convergence innervation requires a modification of the test to avoid fusional strain and diplopia. The eye fixing the Snellen chart has the minus spheres placed before it, while the other eye is covered and sees only the target on the side arm, not the chart. The arm can be rotated on its fulcrum just under the eye until the target superimposes the Snellen chart seen by the other. This modification removes the objection that the accommodation of the other eye is brought about by the strong innervation for convergence opposing strong fusional innervations.

The graphs in Figure 1 show in diopters how much one eye will accommodate upon stimulation of the other. Patient No. 1 was H. E., a 31-year-old woman, wearing: O.D., +4.25D. sph. ⊂ +0.5D. cyl. ax. 15° = 6/12; O.S., +4.0D. sph. ⊂ +1.25D. cyl. ax. 130° = 6/6. Patient No. 2 was A. D., a girl, aged 19 years, wearing: −0.75D. cyl. ax 90° = 6/6, O.U. Patient No. 3 was A. R., a 16-year-old emmetropic boy with 6/6 vision, O.U.

Figure 2 shows similar tests on myself, aged 34 years, wearing: O.D., −0.75D. sph. ⊂ +0.25D. cyl. ax. 90° = 6/5; O.S., −0.5D. sph. ⊂ +0.25D. cyl. ax. 90° = 6/5. Graph 4 (fig. 2) was produced one month before Graph 5 (fig. 2). The solid line, labeled 100-percent coördination, indicates the situation if fixation and accommodation of the controlling eye on the Snellen chart had been perfect, and if the following eye on the side-arm target had been equally stimulated and exactly measured. It is evident that the recessive eye follows the level

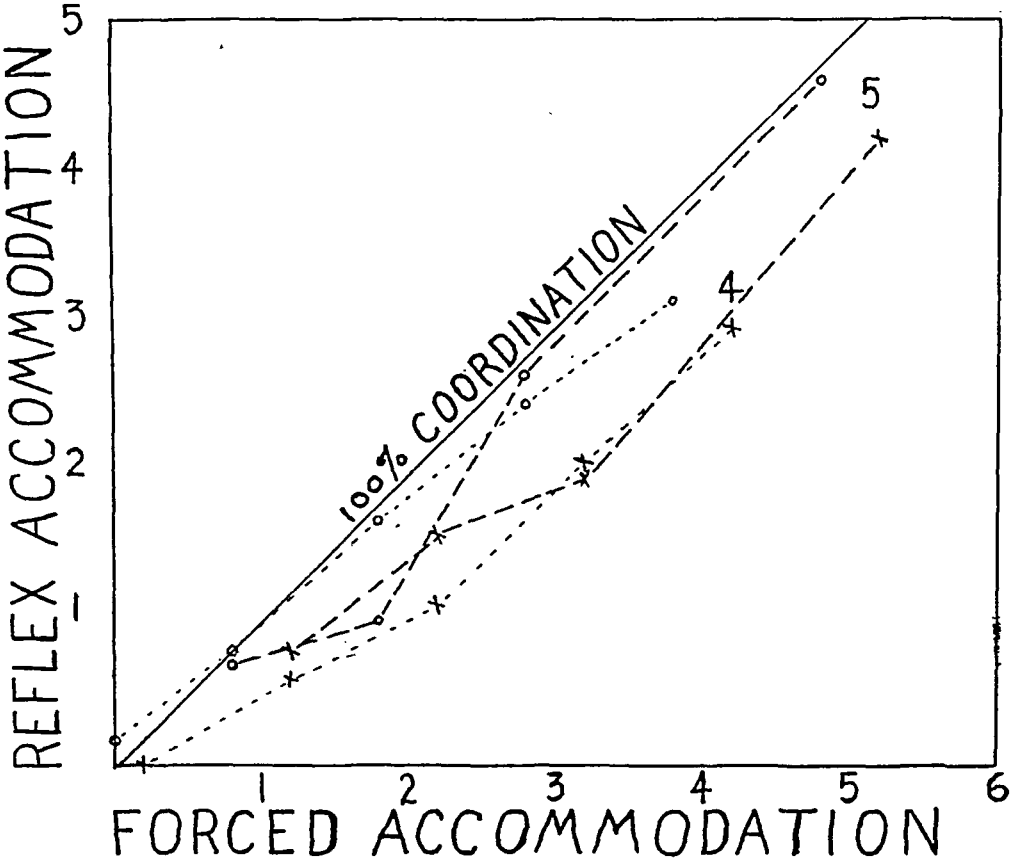

Fig. 2 (Miles). Data from subject P. W. M. Notice that the left eye follows the right better than the right follows the left. The right eye is dominant.

determined by the dominant eye better than the reverse, since No. 1 in Figure 1 is left eyed, and the graph with the left eye being forced to accommodate is nearer the 100-percent line. The cases No. 2 and No. 3 in Figure 1 being right eyed and the case in Figure 2 being right eyed show the graph with the right eye being forced nearer the 100-percent line.

In the refraction of a patient with exophoria by a monocular technique, the lenses chosen will blur him binocularly for distance, since the excess convergence innervation required will produce excess accommodation even at distance. This blur is early detected by use of a binocular technique. Pushing minus in such a case may convert even a tropia into a phoria tolerable to a young patient, although surgery is usually best.

In patients with esophoria it is desirable to "push plus." Binocular technique accomplishes this, since nearly any patient will accept plus binocularly that he rejects monocularly.

Binocular refraction may be misleading in certain patients, particularly those with high ocular dominance, or in whom one eye is constitutionally inferior to the other. The suppressing eye will lack precision, particularly in tests for amount and axis of cylinder. Likewise, on comparing one eye with the other in cyclodamia at the plus 1.5D. fog level, two such eyes will never see equally. Cyclodamia should never require reduction of sphere in one eye more than 0.5D. Moreover, precision is poor at the 6/60 level for the same reason that precision in guessing a meter length is plus or minus a few centimeters, while precision in guessing a centimeter is plus or minus a millimeter or less. The eyes can be best compared at the 6/5 level.

Whatever the method of refraction used, it is important never to blur the dominant eye. The cyclodamia method supposedly ends with the two eyes equal. If one eye is superior to the other, it may be given too much plus to equalize the two. This blur of the dominant eye tends to make it suppress, and the other lead in ocular movements. This is contrary to habits of a lifetime, and leads to confusion and complaint.

It is concluded that in regard to balancing the sphere between nonpresbyopic eyes of average dominance and equal acuity, the binocular technique is valuable.

The second question for consideration is whether the axis of the astigmatism should be determined monocularly or binocularly. This question is discussed very little in the literature. Savage[2] states, "All errors of refraction should be corrected by the examination of only one eye at a time." Curiously enough, he is the man who made himself unpopular because of his obsession with cyclophoria and oblique cylinders. He stated the rule that if minus cylinders lie with the axes symmetrically in the upper nasal quadrants, the axes need to move toward the center of the quadrant to relieve the common excyclophoria due to mechanically weak superior oblique muscles in the reading position. Minus cylinders with axes lying in the outer superior quandrants should be moved toward the nearest axis (90° or 180°) to accomplish the same end.

This rule is impractical because all objects in space do not limit themselves strictly to vertical contours with only vague horizontal lines. Uncorrected oblique astigmatism causes distortion of vertical and horizontal lines of a scissors type, opposite in the two axes. Upon correction, this distortion immediately disappears, and any cyclophoria consequent to the error on view of vertical contours also is automatically corrected. It is important only to align the spectacle cylinder axis with that of the eye in its position of action; that is, under binocular conditions.

This alignment depends upon whether fusional reflex movements of the two eyes are able during refraction to keep whatever target is used imaged upon corresponding retinal points. If this condition is satisfied,

the axes of the spectacle cylinders will align with those of the eye during and after the period of metamorphopsia and "getting used to the glasses." If there is cyclophoria, whether in or out, the axes have been determined in the position they must have to place the images on corresponding retinal points. Monocular refraction fails in this aim, because when one eye is covered it takes its position of rest, and the eye under test may also rotate to its position of cyclorotary rest, being fixed only as to visual direction.

The possibility of cyclophoria makes binocular refraction a necessity in determination of the astigmatic axis.

Another consideration is the physiologic excyclophoria[3a] (12:00 o'clock on the eye rotates laterally under cover) or the monocular physiologic incyclotorsion of the eye in the reading position. This phenomenon is attributed to the mechanical secondary action of the superior oblique muscle in the reading position. Monocular tests should show this incyclotorsion by the change in the measured axis of astigmatism for near, which should not be found on binocular test, due to fusional correction.

In 16 patients with astigmatism, the axis was determined for distance and near both monocularly and binocularly. For binocular determination of cylinder at near, the eye not under test is occluded by a plus sphere just enough to blur out the printed word being used as a test object with the Jackson crossed cylinder. This is usually about plus 3.0D. in the monocular tests, the change in axis from distance to near was toward incyclotorsion 20 times in the 32 eyes, compared to excyclotorsion 5 times, and no change 7 times.

In the binocular tests, the same patients showed incycloversion from distance to near in 10 eyes, excycloversion in 16, no change in 6. This suggests that binocular tests prevent the monocular physiologic incyclotorsion. The amount of change in each instance averaged about 7 degrees. In only 12 eyes did monocular and binocular changes from distance to near correspond in direction.

Comparison of monocular tests to binocular at distance showed change toward incycloversion in 20 eyes, toward excycloversion in 6, no change in 6. The axis changes averaged about 8 degrees.

Some refractionists prescribe cylinders measured in the reading position with the other eye totally occluded. This permits the known incyclotorsion to occur, uncorrected by normal fusional adjustment. The difference may amount to 10 degrees, which is important even in small cylinders. There is also a difference in binocular tests between distance and near. The axis prescribed depends on the patient's occupation, either chiefly distant or near. If the difference is great, two pairs of glasses may be necessary.

Actual clinical evidence that astigmatic axes determined binocularly are more comfortable is difficult to evaluate. Some patients with oblique astigmatism have no complaints at all. Perhaps they suppress, or have less precise fusion demands than others. Some patients can never wear the full prescription over both eyes, even if corrected for aniseikonia.

Axis variation from distance to near is markedly greater in small cylinders than large. This fact, along with other large variations in my data, strongly suggests a large subjective element in the tests. No repeat determinations were made, which would undoubtedly reveal more gross variation.

It may be asked, will an eye the axis of which is not exactly aligned with its spectacle lens in time rotate to align itself in the interest of a clearer image? It is known that the cortical center will initiate a change in the accommodative level to obtain a clearer image. Why will not the reflex mechanism rotate the eye slightly to align with the spectacle cylinder? The obvious answer is that such rotation would throw the retinal images off corresponding points and oppose the fusion mechanism. There is no evidence that, even over the course of years, corresponding points of the two retinas will

change to adapt to different conditions.

It is quite possible that such adaptation could occur in a monocular individual. If not by the reflex mechanism, it could occur by tilting the head, eliciting the ocular righting reaction.

Three patients with astigmatism varying from 2.0D. to 5.0D. were placed before the slitlamp in such a way that they could see a test object clearly 4 feet away. A trial frame with correcting lenses was placed before the eyes so that the observer could see a small portion of limbus of the eye being tested. On slight rotation of the cylinder in the frame, there was no evident movement of small vessels on the limbus in either monocular or binocular fixation. The patients simply reported blur.

Javal suggested testing an astigmatic patient's axis by the novel means of having him tilt the head from side to side. If the blur due to the righting reflex of the two eyes is not equal on tilting the head from one side to the other, the axis should be adjusted until it is. This is possible only in high errors.

Prescription of the spherical equivalent of oblique astigmatism, to reduce the amount of cylinder one fourth or so, will usually give greater comfort. This produces blurred images, which excite less intense fusional innervations, permit less exact fusional movements, and may permit one image to suppress more readily.

Conclusions

It is concluded that binocular refraction is a valuable refinement which permits more exact balance in the sphere between the two eyes, and permits more exact determination of the axis of astigmatism in the position of action.

The method of cyclodamia advocated by Dorland Smith is the most useful method of binocular refraction because the presence of plus sphere before one eye encourages maximum relaxation of the level of accommodation. Other methods have not this advantage, but may be superior in patients with strong ocular dominance.

In the reading position of the eyes, in the usual monocular refraction, physiologic incyclotorsion causes an error in measurement of astigmatic axis amounting to about 10 degrees in small cylinders and about 5 degrees in large cylinders. This error is diminished by the use of a binocular technique, due to fusional movements fixing the eyes in the position of action.

The level of accommodation is kept equal in a pair of normal eyes by a reflex mechanism. Stimulation of one eye will cause the other to accommodate equally even if not stimulated. The fact that the accommodative state of one eye controls the accommodation of the other necessitates the use of binocular refraction.

Binocular refraction is not useful in the absence of fusion, and is less efficient in conditions where one eye is inferior to the other. It should always be used in the determination of the axis of astigmatism, even in amblyopia ex anopsia when fusion is present.

TREATMENT OF SUPERFICIAL CORNEAL INJURIES*

A. Russell Sherman, M.D.
Newark, New Jersey

Different types of superficial corneal injuries vary greatly in their rate of healing. A burn by a curling iron or cooking utensil, or an abrasion produced surgically in the treatment of herpes of the cornea commonly heals in 1 or 2 days. Lime burns and abrasions by fingernails or twigs often require 1 or 2 weeks or longer under some of the usual methods of treatment. It has been my observation that the time required for many of the more stubborn lesions to heal may be greatly shortened and visual impairment reduced in proportion to the rapidity of healing.

For the purpose of this discussion "superficial" corneal injuries are those in which, even though the entire cornea may be denuded, the damage is chiefly to the epithelium, and the stroma remains transparent or almost so. In such cases there is a brilliant stain with fluorescein.

Chemical burns of eyes in which the entire limbal conjunctiva has been severely damaged, in which the cornea is semiopaque, taking fluorescein poorly, and in which there is exudate in the anterior chamber are not included. Such severe burns are fortunately rare, and they are probably best treated by paracenteses as recommended by Oaks.[1]

The importance of superficial injuries is their far greater frequency and the fact that complete recovery of normal vision is possible if there is rapid healing, a condition that is more hindered than helped by certain methods of treatment.

Alkali burns

Any consideration of this subject would be incomplete without references to Hughes's[2] excellent review and analysis of the literature on alkali burns which make up a large percentage of the more extensive superficial corneal injuries.

For years it has been stated that burns by lime leave deposits of calcium-carbonate crystals that cause the corneal opacity often remaining after such injuries, and neutral ammonium-tartrate solution has been recommended to remove the calcium. After reviewing the experimental work on this subject, Hughes concludes that "it is unlikely that calcium ions per se accelerate the progress of the ocular lesion or contribute much to the intensity of the final corneal opacity"; also "it is doubtful whether such calcium deposits are harmful, or whether ammonium salts effectively extract calcium from the cornea." Clinical observation has led me to the same conclusion. I have seen an extensive abrasion, unhealed after two weeks, that had a crystalline appearance resembling calcium deposits, probably the result of scar tissue formation.

In discussing therapy of alkali burns of the eye, Hughes[2] refers to "conservative treatment with irrigation, neutralizing agents, symptomatic therapy" and lists substances which have been recommended as neutralizing agents or for the purpose of extracting lime from the cornea, as well as some substances whose purpose is not clear, such as trinitrophenol ointment, glycerine and water, sugar solution, and many others.

Treatment by bandaging

Regeneration of corneal epithelium is rapid if it is not hindered by the eye and lid movements which necessarily occur during waking hours, and which are increased by repeated instillations and irrigations. I have for some time felt that, after the initial treatment, such procedures are illogical and

* Presented before the Section on Ophthalmology, New York Academy of Medicine, February 16, 1948.

harmful, and that the ideal treatment consists simply of stopping all movement of the eye and of the lids for a few days, an ideal which can most nearly be attained by firm bandaging of both eyes. This is desirable in any case in which as much as one quarter of the epithelium has been lost, especially if the pupillary area is involved.

Preliminary treatment

If the caustic substance was in solution when it entered the eye, it has usually been already washed out by the tears when the patient is first seen by an ophthalmologist, so that further irrigation is unnecessary. Solid particles must, of course, be removed as quickly as possible by forceps, swab, and generous irrigation. Necrotic conjunctiva should be removed at the same time, but I have never followed the practice of denuding the cornea, described by McLaughlin.[3]

An eye whose cornea has lost all its epithelium and presents the smooth, shiny surface of Bowman's membrane often seems only slightly injured and has surprisingly good vision. Fluorescein should, therefore, always be used when the extent of the corneal lesion cannot be clearly seen without it.

The pupil will dilate widely and quickly in an eye whose corneal epithelium has been damaged and atropine may well be instilled as soon as it is discovered that the corneal injury is fairly extensive. If it is applied alternately with the anesthetic, the pupil will be found to be well dilated by the time first aid has been completed and the patient has been made comfortable and has been given an explanation of his injury and the proposed treatment.

This explanation is most important. The patient and anyone who accompanies him must be told, step by step, what has happened to the eye, what is to be accomplished by treatment, how it is to be accomplished, and why other treatment is ineffective. The accompanying friend, relative, or fellow worker will be helpful in persuading him to follow the recommended treatment, especially if it includes hospitalization, and a demonstration of the denuded area, stained with fluorescein, is often convincing.

It should be pointed out that the injured cornea is similar to an abraded or burned area on the skin, that it cannot heal promptly if there is continued friction over the area, and that movements of the eye and of the lids produce this friction which can be avoided only by keeping the injured and the sound eye closed. The possibility of scar formation and permanent visual impairment resulting from delayed healing should be emphasized.

Hospital treatment

Hospital treatment is advised for any eye whose cornea is about one third denuded, and, except in the case of those who live alone, is usually at first refused. When it is pointed out to a man that he will probably be in the hospital for only 3 or 4 days, that there is to be no operation, and that the purpose of going to the hospital is only to have some one wait on him while his eyes are covered, instead of being an additional burden at home, he will often consent to hospitalization.

In the case of those who persist in refusing hospitalization or who can be cared for at home, a modification of the bilateral bandaging may be made. Only the injured eye is bandaged, and the patient is given a dressing which is to be fastened over the other eye, except when eating. He is given a prescription for 3 or 4 tablets of morphine sulfate, and instructed to go to bed, take one of the tablets at once and a second one in the early evening. One must be insistent about the sedative, otherwise the patient who "can stand pain" will spend a restless night, and probably remove the dressing so that he may apply home remedies.

After 12 to 18 hours, the pain usually subsides. There is no reason to inspect the eye for 2 days. The patient is instructed to

stay in bed during this time and, if the bandage is in position and he is comfortable, for an additional day or two. When the cornea no longer stains with fluorescein, or stains very faintly, he is given a snug-fitting black patch, with cotton beneath, to keep the eye closed, and a bland ointment to be applied several times daily for a few days.

still showed any staining with fluorescein are indicated.

Both 1 P. K. and 2 M. F. are from patients who had a corneal burn by wet lime. The injured eye was bandaged and the uninjured eye was covered with a dressing at home, 3 J. B. and 4 J. H. illustrate burns by dry lime that were treated by binocular

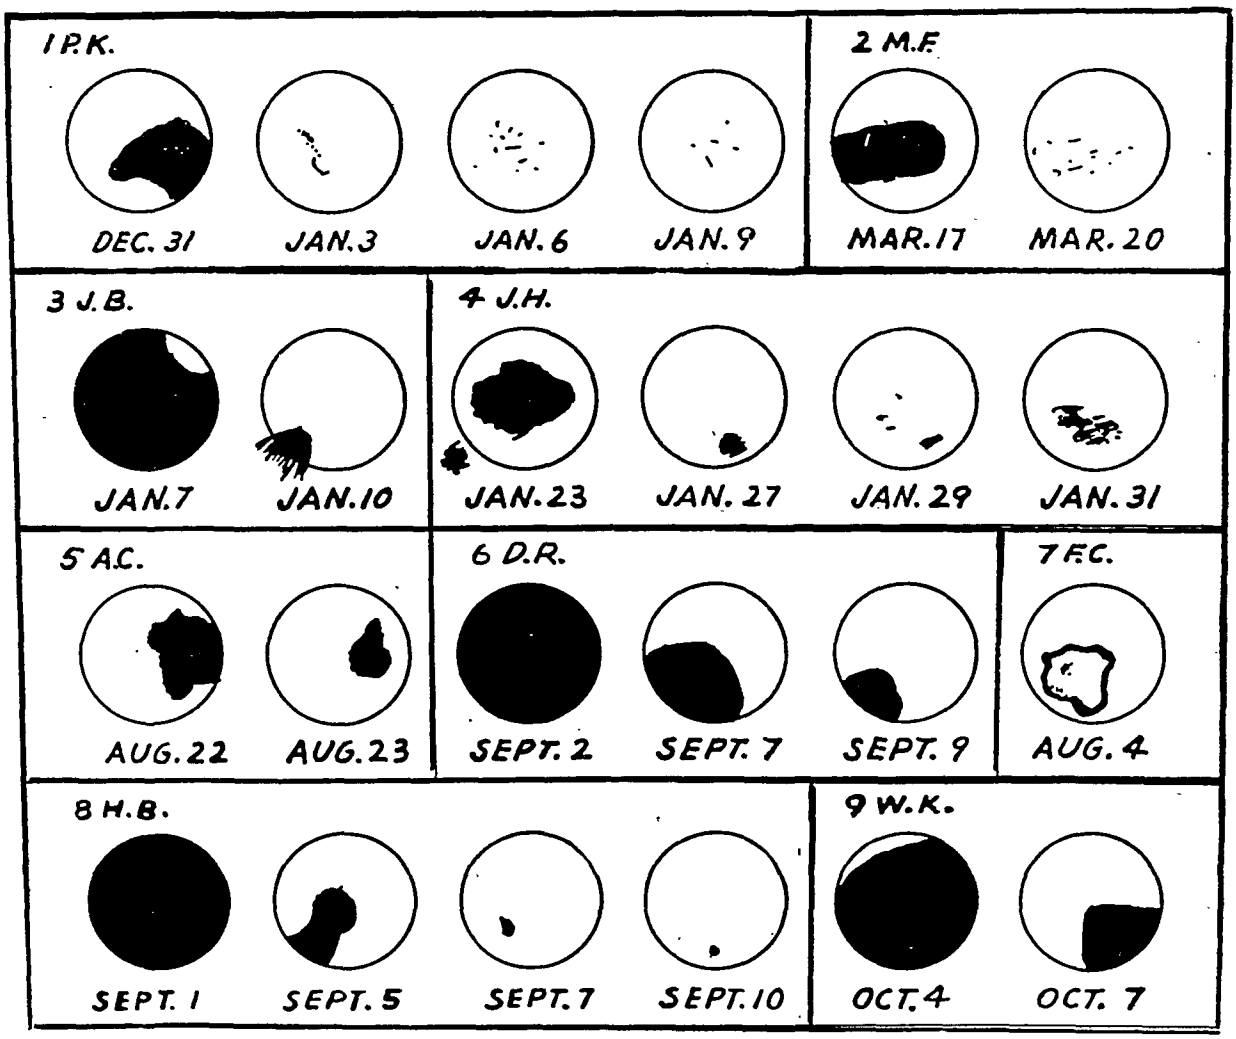

Fig. 1 (Sherman). A chart indicating the rate of healing in nine cases of extensive superficial corneal injuries treated by binocular bandaging. (Cases 1 P. K. to 9 W. K.)

Case reports

In Figure 1, the diagrams labelled 1 P. K., 2 M. F., 3 J. B., 4 J. H., 5 A. C., and 6 D. R. show the rate of healing in 6 patients with lime burns of moderate to moderately severe intensity. The dates of the first and each successive examination while the cornea

bandaging in the hospital. Case 4 J. H. had a craterlike burn in the bulbar and in the superior palpebral conjunctiva, in which lime particles were embedded.

Cases 5 A. C. and 6 D. R. (fig. 1) represent burns by wet plaster, treated by binocular bandaging in the hospital. Case 6 D. R.

had a burn which would be considered severe by any standard since the entire cornea was denuded. It had healed by the 12th day, but a faint central scar remained and the visual acuity 7 months later was reduced to

ing which time the eye had been treated by the usual conservative methods. There was nothing to suggest that the injury had originally been any more severe than those in cases 1 P. K. to 6 D. R. (fig. 1) or that it

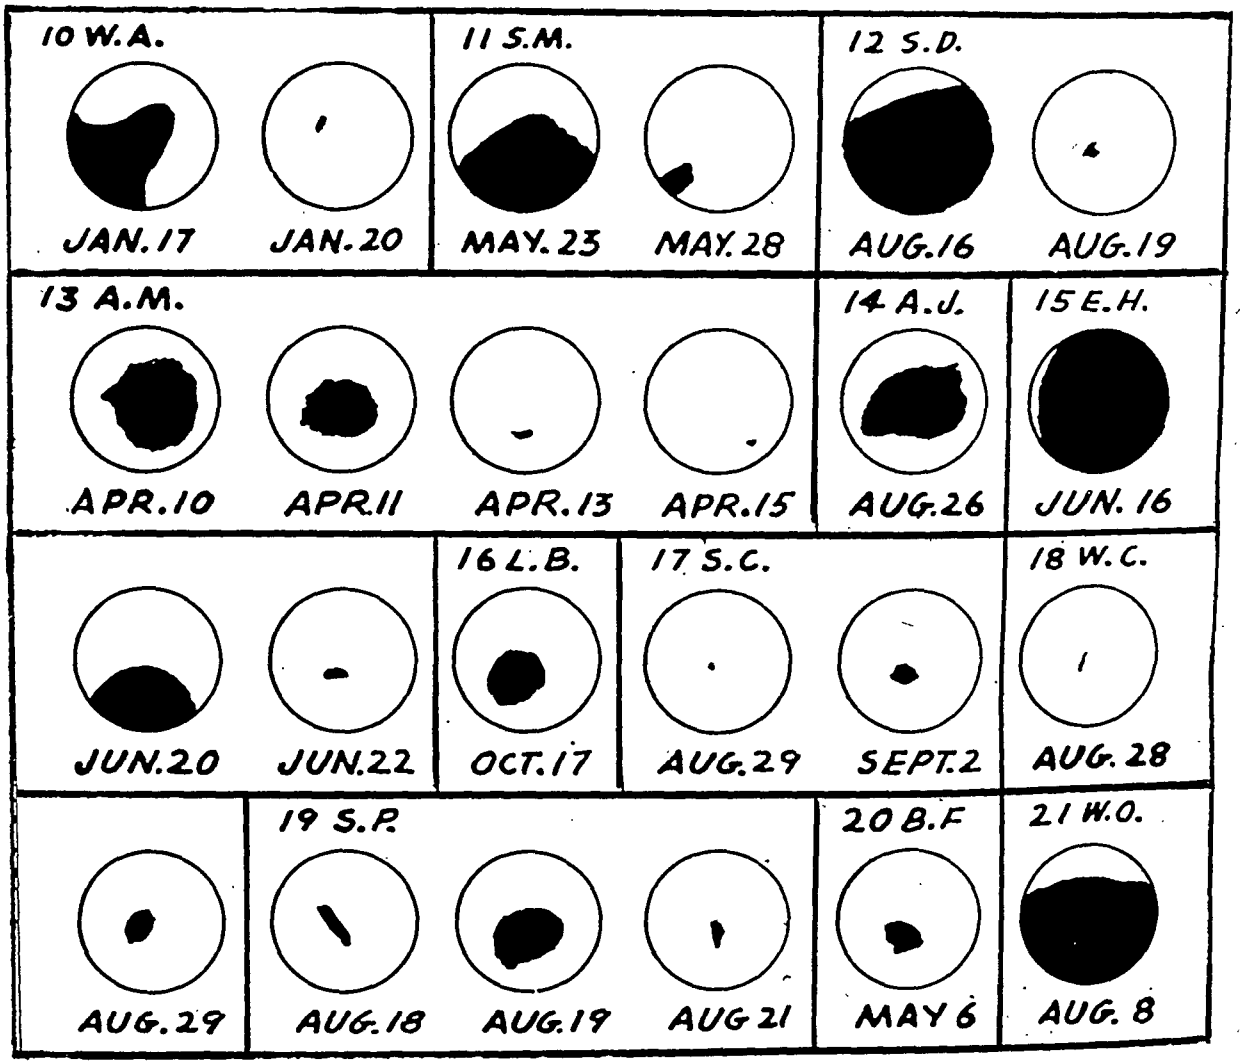

Fig. 2 (Sherman). Twelve cases (10 W. A. to 21 W. O.) are represented in this chart illustrating the rate of healing.

20/38. The other cases had no residual corneal opacity.

Cases 3 J. B. and 6 D. R. (fig. 1) illustrate an interesting feature of the healing of moderately severe burns with damage to the limbal area; namely, the failure or marked retardation of epithelial regeneration from this area.

The patient represented in 7 F. C. (fig. 1) was burned by wet plaster. He was not seen until 2½ weeks after the injury, dur-

would not have healed as quickly with similar treatment.

There was the staining area shown in the diagram, with a raised border, as if the proliferating epithelium, having been prevented from growing across the denuded area, had piled up around it. The cornea healed after three months' treatment which included bandaging, curetting the raised edges, application of iodine to the denuded area, and covering with a conjunctival flap,

none of which procedures had any noticeable effect. The final vision was 10/200. There was no symblepharon or other conjunctival lesion suggesting that the injury was of greater severity than in the first six cases, and with the same initial treatment, there would probably have been just as rapid healing. Lesions caused by other common caustics heal equally rapidly when treated by occlusion.

Figure 1 (8 H. B.) shows the rate of healing of a cornea which was burned by 50-percent sodium-hydroxide solution, and Figure 1 (9 W. K.) that of a cornea burned by potassium hydroxide.

Figure 2 (10 W. A.) is from a patient with a burn by muriatic acid and 11 S. M. represents a sulfuric-acid burn, sufficiently severe to cause scarring of the conjunctiva of the upper lid. Figure 2 (12 S. D.) is a burn by concentrated sodium-peroxide solution, and 13 A. M. is a liquid sulfur-dioxide burn.

In 14 A. J. (fig. 2) the extent of the denuded area of a cornea burned by carbon tetrachloride is shown. No healing had taken place after 24 hours of monocular bandaging, but after 3 days of binocular bandaging, healing was complete.

The extent of denudation of a cornea burned by mercuric iodide solution is shown in 15 E. H. (fig. 2). After 48 hours' treatment with a simple dressing there was no change, but with binocular bandaging, healing progressed as indicated.

Discussion

The severity of injuries observed clinically cannot be standardized as one standardizes experimental injuries. Visual acuity certainly cannot be used as a standard, since it may seem to be impaired by some unimportant condition like blepharospasm or lacrimation.

On the other hand, an eye which has lost its corneal epithelium may have good visual acuity, much better than one whose epithelium is in position but is hazy. The extent of epithelial loss may be observed and recorded, but there is no unit of measurement for the extent of corneal opacity, and any attempt to measure and express this factor in grading the severity of a chemical injury will necessarily be inexact.

I believe that the 15 cases of chemical injuries cited in this paper should all be classed as severe or moderately severe. Except for the case represented by 6 D. R. (fig. 1) which presented a complete loss of epithelium from a lime burn, none had any residual visual impairment after treatment by binocular occlusion.

The reasons which make binocular occlusion a logical treatment for chemical injuries of the cornea apply equally to the treatment of mechanical injuries. Among the most troublesome and painful of these are certain superficial abrasions and erosions. The patient suffering from such a lesion is commonly seen after having spent a sleepless night and needs no persuasion to submit to binocular occlusion or any treatment that promises relief.

Treatment of corneal abrasions

Binocular occlusion has been satisfactory in the treatment of several patients with corneal abrasions which did not heal with "open" treatment, or which would have been expected to be slow in healing.

Case reports

Case 16 L. B. (fig. 2) had an abrasion by a fingernail. He was sent home with both eyes bandaged and the cornea was healed when he was next seen four days later.

Case 17 S. C. (fig. 2) had a foreign body in the cornea that was removed by a foreign-body gauge, used in the manner that one uses the corneal burr. He returned after 4 days with a painful erosion which healed after 2 days at home, with the injured eye bandaged and the uninjured eye closed by a dressing.

Case 18 W. C. (fig. 2) had a superficial wound from a nail. The pupil was dilated

and a dressing applied. The following day the denuded area was much larger and the eye very painful. A bandage was applied and he was given a dressing for the other eye. Four days later he returned with the cornea healed, stating that the eye had become comfortable within 24 hours.

Case 19 S. P. (fig. 2) had an abrasion caused by the end of an airhose. After dilatation, a dressing was applied and he was told to keep his other eye closed at home. He returned to work, however, and the following day about one quarter of the cornea was denuded. The eye was bandaged and he went to bed at home. Healing was complete after 4 days.

Case 20 B. F. (fig. 2) was seen in consultation 10 days after something entered his eye while he was taking down storm-windows. Under customary treatment with atropine, antiseptics, and hot compresses, the condition had become steadily worse. The eye was bandaged and he was advised to stay in bed with the other eye closed. He was not seen again, but reported 18 days later that the eye had become comfortable within 2 days.

Case 21 W. O. (fig. 2) was seen August 8th in consultation at the hospital to which he had been admitted for treatment of a most extensive erosion of the cornea, following an injury by a needle 13 days before. After 4 days of binocular bandaging, there was complete healing and he left the hospital, but was readmitted 3 days later because of a recurrence of the erosion, which healed after 2 more days of binocular bandaging. The affected eye was kept bandaged for another 2 weeks to prevent further recurrence. When he was examined September 11th, there was a diffuse haze over the lower two thirds of the cornea.

Comment

Before the eye is bandaged, the pupil is, of course, dilated with atropine and a local anesthetic, usually nupercaine, is applied. Morphine is still the most reliable analgesic and hypnotic. Its use during the first day or two is an essential part of this treatment which, to repeat, is based on the fact that corneal epithelium regenerates rapidly, and the idea that this regeneration may best be encouraged by preventing lid and eye movements.

Summary

1. Certain superficial traumatic lesions of the cornea are characteristically slow in healing.

2. This delayed healing results in corneal opacities from scar-tissue formation, which can be prevented by rapid regeneration of corneal epithelium.

3. Corneal epithelium tends normally to regenerate rapidly and the treatment most likely to encourage this regeneration is to abolish movements of the eye and lids by binocular bandaging.

4. Twenty patients with extensive superficial corneal injuries and one patient with an entirely denuded cornea who were treated by this method are described, with charts indicating the rate of healing.

EDWARD LORENZO HOLMES*

Pioneer Chicago Eye Doctor

E. V. L. Brown, M.D.
Chicago, Illinois

Many biographical sketches are too factual. They deal too much with what their subject did rather than the why and how he did as he did. The present sketch will therefore aim to understand and explain its subject rather than to tell in too great detail just what he did.

The essential facts are about as follows:†

Edward L. Holmes was born in Dedham, Massachusetts, near Boston, in 1828; attended the village school; prepared for, attended, and was graduated from Harvard College in 1849; taught Latin, Greek, French, and mathematics at the Roxbury Latin School for two years, then returned to Harvard Medical School and, after a three-year course, was graduated in 1854. He spent the next year as surgical resident at the Massachusetts General Hospital and followed this with a year and a half of study of the eye and ear in Paris and Vienna. He then located in Chicago late in 1858 and practiced ophthalmology and otology here some 44 years until his death in 1900.‡

Shortly after coming to Chicago, he joined the faculty of Rush Medical College, then in its 13th year, and two years later established the Illinois Charitable Eye and Ear Infirmary.

Holmes had more than a dilettant interest in things basic to ophthalmology. I started work in the Rush Eye Clinic in 1898, the year Dr. F. C. Hotz succeeded Holmes as head of department, and I soon ran across a series of 30 or 40 eye specimens prepared by Holmes in a unique way.

For the most part they demonstrated gross changes—tumors, ectasias, and foreign-body effects, such as phthisis bulbi and atrophy bulbi. But their permanent labeling clearly demonstrated Holmes's interest and his ingenuity. He had hammered out a number for each specimen on a 1 by 4 cm. thin slab of lead and placed this slab beside the specimen in alcohol within a well-stoppered bottle. A little later I spent many weeks just trying to make out numbers and identifying hundreds of other specimens at the Infirmary where Holmes's successors had left them in a sad state. He was both careful

---

* First presentation under the gift of the Rudolph Wieser Holmes and Maria Baxter Holmes Fund in Memorial to Edward Lorenzo Holmes. Read before the Institute of Medicine of Chicago, at a joint meeting with the Chicago Ophthalmological Society and the Society of Medical History of Chicago, January 30, 1948.

† An excellent article on "Edward Lorenzo Holmes" was written by Dr. Arthur Tenny Holbrook and published on "The Corpuscle," March, 1900, pp. 273-283, and is to be found in the Rush Medical College Library, Chicago.

‡ Being an ophthalmologist, I will not attempt to evaluate Holmes as an otologist.

and resourceful, and he was definitely interested in eye pathology.

Although he wrote over 50 interesting and valuable articles, some of which were translated into German, it cannot be said, if rigid standards are used, that Holmes left any significant writing. Holmes was, however, of great significance to the culture of his city and time, using culture in a broad sense. One commentator says that he was the most significant Chicago medical man of his time.

In addition to the Infirmary, Holmes helped to establish the Presbyterian Hospital and was the one most responsible for its affiliation with Rush Medical College. He was one of the founders of the Chicago Historical Society and of Unity Church and was very widely known as an amateur musical critic. I have also learned that Dr. Holmes was the one who first proposed the affiliation of Rush Medical College with the University of Chicago. He brought his idea before the Rush trustees and Dr. E. Fletcher Ingalls was delegated to take the matter up with President William Rainey Harper in the late 1890s.

Holmes's special talent evidently lay along the lines of institutional management and development, for he soon became a head of the department at Rush and eventually served eight years as president of the college (1890-1898) during one of its periods of most energetic growth, the one just preceding 42 years of affiliation with the University of Chicago. His capacity as an administrator is shown by the fact that 15 years after he started the Infirmary, Holmes and others were able to convince the state of Illinois that the state should buy and take over the Infirmary as a state institution (1871).

It has taken Holmes's successors 75 years to make any further move in the vital interest of this important institution, namely, to sever its medical and administrative management from the semipolitical control of the Department of Public Welfare and place its professional and administrative control in the hands of the state university where it has long belonged.

Looking for the unusual in any outstanding man, one naturally turns first to his parentage. In Holmes's case we find good substantial God-fearing English-New England stock. His father was a machinist and had his own shop. His mother was the granddaughter of the "For-God's-sake-fire" Major Buttrick who led the Minute Men at Concord.

On the side of environment there was a great deal that was very favorable, even if fortuitous, for he grew up close to the Harvard and Boston of the 1840s and 1850s with its Emersons and Thoreaus, Lowells and Longfellows. In any case, for one reason or another, this boy and youth had something which made more than one unusual person anxious to help him.

Some incidents show rather clearly. Thus Holmes's taste for books and learning was stimulated at the age of 14 years, when Motely, the Harvard historian, asked him to help unpack a lot of books. Here were books in German and French. The queer-looking Russian intrigued Holmes. Next, the well-to-do father of one of his boy friends wanted to have his son tutored and asked Holmes to join in, and eventually Edward Holmes obtained three years of unusual preparation for Harvard in this way.

In these formative years he had an unusual set of teachers. Included were Charles A. Dana, later editor of the *New York Sun*, who taught him Greek; Elijah Howe and John E. Dwight, Latin; George Ripley, literature—all men of great erudition and culture. One spring and summer were spent at the famous Brook Farm colony.

Evidently, too, Holmes had a good voice, for he sang in the village choir at home and later, as a Harvard student, in the combined city-wide Cambridge church choirs. So it came about that one Alexander W. Thayer asked him to hear a Haydn oratorio of a

Saturday afternoon. Not knowing what an oratorio was Holmes accepted, and throughout his whole life continued to hear and enjoy every musical affair he could.

In college, Holmes deliberately stressed the languages, both ancient and modern, although mathematics and science were his bent. With a fellow student he bought a "key" or "pony" for the German course. The instructor was somewhat surprised at the perfection of their exercises, became suspicious, and gave them searching oral drills day after day. But they had also memorized the material and so impressed the teacher that he asked them if they were especially interested in German. When he received an affirmative reply, he offered to read Wilhelm Tell with them during an hour he had free three times a week. They surprised themselves with their progress.

Much the same thing happened with Longfellow who offered to read *Gil Blas* with them in his free hours three times a week. And some years later in Paris, a gruff, unfriendly American sculpture student, eating at the same table with Holmes, burst out with an offer to explain the pictures in the Louvre to him. They spent many hours there together to Holmes's great profit. These are only minor incidents. But they bespeak an attractive, eager personality, one which encouraged people to go out of their way to enjoy association with the individual.

After a year and a half in Paris and Vienna under the influence of Albrecht von Graefe, the greatest ophthalmologist of all time, and of Virchow and Helmholtz, with Graefe's iridectomy for glaucoma and Helmholtz's ophthalmoscope only 5 or 6 years old, Holmes came to Chicago, then a town of only 30,000, in 1858, on borrowed money, made a place for himself, and was able, within 2 or 3 years to loan $4,000 to the Infirmary, a sum the state later paid back.

He interrupted his busy life to make a trip back to Vienna and marry, when 34 years of age, a charming, musically talented woman of the lesser nobility. Returning to Chicago, he engaged in all the cultural activities possible to one of his make-up and time.

With these facts in mind, may we not say that Edward Lorenzo Holmes was an ideal pioneer Chicago eye doctor, one whose well-rounded life we can contemplate with satisfaction and profit, a man whom we can honor and admire, and one whose memory this Institute does well at this time, a hundred years later, to perpetuate.

122 South Michigan Avenue (3).

NOTES, CASES, INSTRUMENTS

AN UNUSUAL CASE OF PROGRESSIVE MELANOSIS OCULI

CARL D. F. JENSEN, M.D.
AND
GILBERT N. HAFFLY, M.D.
Seattle, Washington

Ocular melanomas steadfastly resist the efforts of our best ophthalmologists to raise the iron curtain that jealously guards the origin, the course, and the prognosis of these potentially dangerous tumors.

Bouqien,[1] in 1917, made the first great stride toward recognizing the congenital forms of melanosis oculi. His classical description of the "true and constant signs and characteristics of hereditary melanosis" stimulated the interest of his contemporaries in reporting unusual cases of ocular discolorations and growths. Ophthalmologists began to become increasingly aware that early recognition of benign and malignant melanomas together with the precancerous and cancerous melanotic states meant life or death to the patient.

It remained for Reese[2] to direct the attention of his colleagues to the clinical and pathologic recognition of precancerous and cancerous melanotic states with his analysis of 17 of his own cases which included one case of spontaneous regression. Recognizing that the whole subject of pigmented tumors is "in a state of flux," Reese[3] recently has attempted to replace the indiscriminate use of the term "melanoma" for all pigment-bearing tumors with a suggested terminology based on histologic findings that disregards the prominent pigment factor common to all such tumors.

This attempt to establish a degree of order in a controversial and chaotic subject is a courageous step forward in the right direction. Unfortunately there are certain cases which defy any convenient attempt to pigeon-hole them clinically or histopathologically. We wish to present one such case.

CASE REPORT

History. L. E., a married Chinese man, aged 40 years, with two entirely normal children, aged 8 and 10 years, was first seen in October, 1946, with a pigmentary disturbance of the right eye, the right side of his face, and the right side of his forehead and scalp. He had no physical or ocular complaints and was unaware that the excessive pigmentation was remarkable. He had been born in China of nonconsanguineous parents. He had had the usual childhood illnesses. He had come to the United States at the age of 10 years.

When questioned about the duration of the pigmentation, he stated that his parents had noticed a small pigmented area on his right eyeball when he was approximately five years of age. This pigmented spot slowly became larger during the first two decades of life. However, at 17 years of age, the pigmentation was still confined to the right globe. In his early twenties pigmentation of the upper and lower right eyelids began to appear. During the past two decades the pigmentation has spread extensively over the right side of his face, nose, brow, forehead, and the parietal and occipital portion of his scalp.

General physical examination. Entirely negative except for the abnormal pigmentation to be described.

Face. There was a diffuse slate-gray, nonelevated pigmentation irregularly spread over the right side of his face, extending through the floor of the nose into the mucous membrane of the mouth. In the mouth the pigmentation was confined to the region of the hard palate. The overall pigment picture might be likened to the end result of a severe powder-blast burn.

Ophthalmic examination. Uncorrected

visual acuity was: O.D., 20/20; O.S., 20/20. Cycloplegic refraction showed: O.D., with a −1.25D. sph. ⊂ +2.0D. cyl. ax 90° = 20/20; O.S., with a +0.25D. sph. ⊂

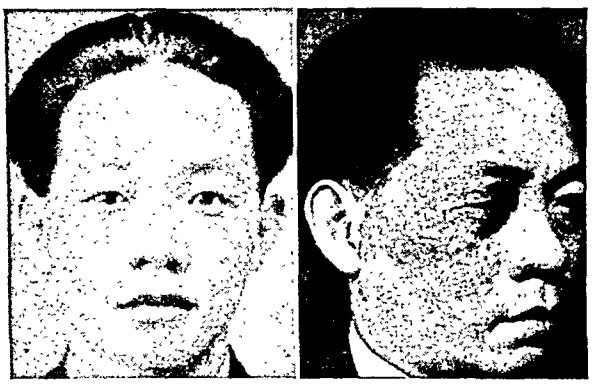

Fig. 1 (Jensen and Haffly). The patient at the ages of 17 and 40 years. (Left) Small pigmented area confined to the right globe. (Right) Side view of face showing the irregular patchy distribution of the lesion.

+0.75D. cyl. ax 60° = 20/20. Tension was 18 mm. Hg (Schiøtz).

Right Eye

Conjunctiva. Diffuse, irregular patches of grayish-black pigment were scattered throughout the bulbar conjunctiva, becoming more confluent in the region of the fornices. This pigmentation was continued into the palpebral conjunctiva to the lid margins.

Sclera. A diffuse bluish-violet discoloration occupied the majority of the visible sclera.

Cornea. The cornea was clear macroscopically. Slitlamp examination revealed infiltration of pigment granules that extended from the sclera a millimeter or more into the corneal stroma at the limbus.

Iris. Pupillary responses were normal. The iris had a deep, rich-brown color with a velvetlike sheen. The heaviness of the pigment granules present made the iris trabeculas indistinct. The iris color was much darker than that of the left eye.

Ophthalmoscopic examination. The media were clear. The fundic reflex of the right eye was dull as compared with the left. The

Fig. 2 (Jensen and Haffly). Close-up view of the right eye showing the bluish-violet and grayish-black patchy distribution of pigment.

macular area and the retinal vessels appeared normal. The optic disc had a deep physiologic cupping. Within the depths of the physiologic cup were scattered flecks of black pigment, interlacing with the weblike network of the strands of the lamina cribrosa.

Left Eye

The findings in the left eye were entirely normal with the sole exception of the presence of an isolated clump of rich-brown pigment approximately 1 by 1 by 1 mm.

Fig. 3 (Jensen and Haffly). The right eye with speculum in place.

lying on the surface of the iris in the 5:30-o'clock position, midway between the chamber angle and the pupillary margin. This elevated pigmented area had the same rich-brown color as the entire iris of the right eye and was much darker than the remainder of the iris.

Microscopic examination

The microscopic report of a section of skin taken from the margin of the lesion on the forehead read: "A piece of skin including all of the cutis. The epithelium is not remarkable. Throughout the corium are numerous cells varying from stellate to fusiform in shape, filled with brown pigment. They are dispersed, typical of chromatophores filled with melanin. There is no clumping or other features of a blue nevus. There is no evidence of malignancy."

Fig. 4 (Jensen and Haffly). Photomicrograph showing pigment-ladened chromatophores in corium. There is no evidence of melanotic nevus. (×200.)

Comment

This lesion may properly be called a nevus, if one uses this as a generic term to include any congenital discolored lesion of the skin. It is not the common type of neuronevus, the cells of which resemble epithelial cells and are probably neural in origin. These cells usually contain melanin. Such a lesion may undergo malignant transformation to become a malignant melanoma.

In the present case the histopathology may be likened to that of the Mongolian spot in which the pigment may be increased in the epithelium, being particularly noticeable in chromatophores, scattered throughout the corium. When such heavily clumped pigmented chromatophores band together in discrete nodules, the term "blue nevus" is usually employed. Thus there is much similarity between the histopathology of the Mongolian spot and the blue nevus. In the present case the lesion is diffuse and, histologically, the chromatophores are not clumped into nodules. It would seem unwise to use the term "blue nevus" for the diagnosis. The term "melanosis cutis" would seem to be an adequate diagnostic term for the skin lesion in this case.

Discussion

This case seems without parallel in the medical literature. Reese[4] states that he has never seen a similarly advanced case and adds that it may well represent a precancerous melanotic state. Whether one is dealing with an acquired diffuse precancerous lesion that will develop in time into a malignant melanoma or whether one is merely witnessing the widespread development of a benign congenital condition that has gained momentum with the passing years, can only be a matter of conjecture. Microscopic studies of a skin section taken from the advancing margin of the lesion reveal no evidence of malignancy in the area of biopsy. In many ways the findings fit Bouqien's classical description of congenital melanosis oculi that includes the following characteristics:

1. Brown to blackish iris with no evidence of trabecular structures. The iris may assume a velvety appearance.

2. Dark iron-gray color of the fundus without any evidence of transillumination of

the choroidal vessels and intravascular spaces.

3. Pigmented spots in the conjunctiva.

4. Spotty diffuse discoloration of the sclera surrounding the cornea.

5. Pigmentary deposits in the optic papilla.

6. Discoloration of the skin of the lids.

7. The refracting media, as well as the nervous part of the retina, are not affected.

8. Occurrence is more frequent in individuals with dark complexion and dark hair.

9. Usually monocular.

SUMMARY

An unusual case of excessive pigmentation of the right globe, right optic papilla, right side of the face, right side of the scalp, and the roof of the mouth is presented with suitable pictorial evidence that the widespread disturbance was not present when the patient was 17 years of age.

Microscopic studies reveal a benign pigmentation of the skin made on a biopsy of the advancing margin of the lesion. In the absence of more definitive findings it is felt that the case should be considered one of benign progressive melanosis oculi. It is entirely possible that this widespread pigmentary disturbance represents a precancerous melanotic state. Only time can tell.

PLASTIC REPAIR OF A CONGENITAL DEFORMITY OF THE EXTERNAL CANTHUS

VITO LA ROCCA, M.D.
New York

Malformations of the external canthus are usually acquired through burns or injuries of the temporal region followed by retraction of the scar tissue. Very seldom are slight deformities observed as congenital anomalies, and the literature on the subject is very poor; in fact, no description is found of cases similar to the one herein described.

In 1938, Wheeler described an interesting case with complete absence of the external canthus ligament. In order to rebuild the canthus in proper position, he had to use two strips of orbicularis that were brought close to the periosteum of the zygomatic bone.

In the case which I am about to describe, the ligament existed but was ectopically implanted at the margin of the zygomatic bone, about 1 cm. lower than the normal position. Because of this abnormal insertion, the lower lid was pulled down and forward, leaving a space between the lid and the eyeball. Even when the patient's eye was tightly closed some part of the cul-de-sac was exposed and a moderate lagophthalmos was present.

A plastic operation which would correct the deformity had to deal both with the external canthus ligament, by transplanting it to its right place, and with the skin of both lids, because when a manual traction was done to raise the external canthus to the

level of the one of the left eye, there was a bulging in the skin of the upper lid and a pulling downward by the stretched skin of the lower lid.

Case report

M. N., a woman, aged 20 years, was first seen in my office on October 3, 1945, for

Fig. 1 (La Rocca). Congenital deformity of the external canthus.

Fig. 2 (La Rocca). Appearance after plastic correction.

the condition of the right eye already described and illustrated in Figure 1. The patient was admitted to the New York Eye and Ear Infirmary on October 19, 1945, for plastic repair under local anesthesia. After infiltration of the region with novocaine (2 percent), a flap of skin 2½ cm. long and 1 cm. wide was delimited on the outer part of the upper lid; an incision of the same length was made in the skin of the lower lid parallel to the palpebral margin (fig. 3). The external ligament was exposed and completely detached from its attachment to the lower margin of the orbital rim. A double-armed silk suture was passed through the conjunctiva, the tendon of the external ligament, and then through the periosteum of

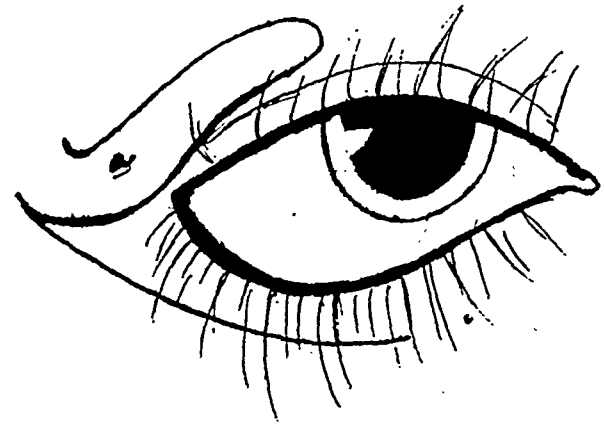

Fig. 3 (La Rocca). A skin flap (a) is delimited on the outer side of the upper lid and an incision of the same length is made in the skin of the lower lid.

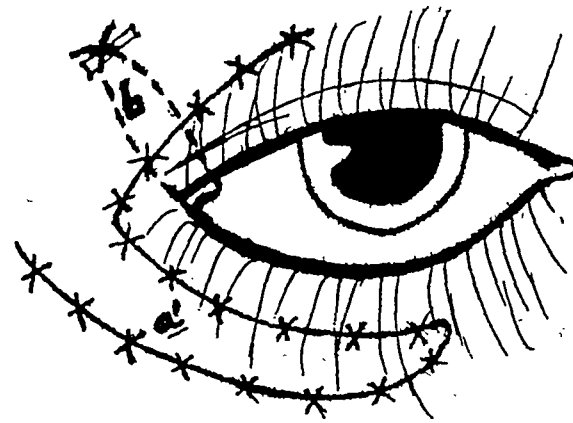

Fig. 4 (La Rocca). The skin flap (a') is swung from the upper lid and sutured into the bed previously prepared in the lower lid. A double-armed silk suture (b), tied over a rubber peg, pulls up the external canthus.

the zygomatic bone, 1½ cm. higher than the original insertion. This suture was tied over a rubber peg, near the tail of the eyebrows.

The skin close to the incision of the lower lid was then undermined to make a bed for the flap which was swung from the upper lid and sutured with several fine cataract

silk sutures. A light pressure bandage was applied and the patient was discharged from the hospital after 24 hours. The heavy silk suture supporting the canthal ligament was removed on the 10th day, while the fine sutures were allowed to fall by themselves. Recovery was uneventful. The appearance was improved as shown in Figure 2, and the lagophthalmos disappeared as soon as the lid was brought near to the eyeball.

SUMMARY

An unusual case of congenital malformation of the external canthus with lagophthalmos is described. The correction was obtained by lifting the external canthal ligament to a proper position, plus a skin flap taken from the upper lid and transplanted into the lower lid to diminish the traction of the lid downward and eliminate the lagophthalmos.

SQUAMOUS-CELL CARCINOMA OF THE ORBIT

S. B. FORBES, M.D.
Tampa, Florida

The case of squamous-cell carcinoma of the orbit here described presents several unusual features. A comprehensive review of the literature revealed no similar case. First, this type of tumor is almost unknown in this location. Secondly, the earliest symptom was diplopia, for which extraocular muscle surgery was done with an apparently successful result. There was no recognition of any unusual pathologic change in the region of the internal or lateral rectus muscles at the time of the original operation. Thirdly, the late symptom of blurring of vision was complained of by the patient, despite rather recent refraction, approximately 10 months after the original operation. The refractive change in this case illustrates the possible role of this evidence in differential diagnosis.

REPORT OF CASE

History. H. R., a florist, aged 53 years, complained of pain in the eyes almost constantly and double vision on looking to the right, for the last three months. The diplopia was not present in any other position of the eyes. He had received injections of thiamin and penicillin and had taken some thiamin by mouth.

There was a history of many skin cancers removed by irradiation, particularly a large growth in the right temporal region within the four years immediately preceding. The patient was of fair complexion, and there had always been great intolerance on exposure to sunshine. He had no unusual habits, vocations, or avocations, and the family history was noncontributory.

Eye examination. On January 11, 1946, ocular examination showed that the bulbar and palpebral conjunctivas were normal. There was greatly limited external rotation of the right eye and a tendency to close this eye in the right lateral position. The pupillary size, shape, and reactions were normal. The eyegrounds gave evidence of moderate arteriolar sclerosis. The media were clear. Vision of 20/30 in both the right and the left eyes was corrected to 20/20 with the following combinations: R.E., +0.25D. sph. ⊂ +0.5D. cyl. ax. 127.5°; L.E.; +0.5D. sph. ⊂ +0.5D. cyl. ax. 82.5°; with a +2.0D. sph. addition, J1 was obtained in each eye.

The accommodative power was equal and normal in both eyes. The near point of convergence was normal. Esotropia of 8 prism diopters was present in the primary position with no vertical component. There were 10 prism diopters of esotropia at near.

A homonymous diplopia was present in the primary position, exaggerated in the right lateral position of the eyes and disappearing almost entirely in the corresponding position on the left. A 5-degree prism, base out, fused images on the red-glass test in the primary position, while in the right lateral

position it required a 15-degree prism, base out, for fusion.

The palpebral fissures were equal in the two eyes, and the exophthalmometer readings were the same for both. The peripheral visual fields were normal for form and color during the entire course of the disease, as were also the central fields and blindspots.

There were many flat glistening skin scars scattered over the body with a large scar, measuring 4.5 by 5 cm., in the right temporal region just above the external angle of the orbit. These were postirradiation scars, resulting from treatment of the skin cancers.

Diagnosis of palsy of the sixth nerve on the right side was made. The patient was referred for a neurologic examination, which gave negative results, including examination of the spinal fluid.

When the patient was seen 19 days later, the ocular findings were about the same. There was, however, the additional complaint of drooping of the right upper lid. This symptom was not verified, for the palpebral fissures were, as before, equal, 14 mm. on the two sides. An injection of prostigmin was given, but there was no alteration in the width of the fissure nor any change in the heterotropia. The exophthalmometer readings were still equal. The apparent ptosis complained of was then ascribed to the involuntary closure of the right eye in order to overcome diplopia.

Two months later the diplopia had about doubled in degree. On May 29th, a 7-mm. resection of the lateral rectus and a 3-mm. recession of the mesial rectus were performed. The postoperative course was uneventful.

Orthoptic exercises were given until July 2nd. At that time the following prescription for glasses was given: R.E., +0.5D. cyl. ax. 97.5°; L.E., +0.75D. sph. ⌒ +0.5D. cyl. ax. 105°. Vision of 20/20 was obtained in each eye at distance, and at near with the addition of a +2.25D. sph. a J1 was easily obtained in each eye. There was exophoria of 2 degrees at distance in the primary position and of 8 degrees at near. Slight diplopia of the heteronymous type was present at distance, particularly in the left lateral position. The segments in the glasses were decentered in, and convergence exercises were prescribed for home use.

In December, 1946, the patient reported for treatment for a moderate conjunctivitis. Conjunctival smears were negative for organisms, as were cultures in blood agar and in broth. This condition responded to treatment and soon subsided. The operative scars showed nothing unusual.

On February 24, 1947, on complaint of the patient, another refraction was done with the following findings: R.E., +0.5D. sph. ⌒ +0.25D. cyl. ax. 15°; L.E., +0.5D. sph. ⌒ +0.25D. cyl. ax. 120°. Reading addition, O.U., +2.25D. sph. The external deviation was about the same at distance and near. The patient was advised to continue the convergence exercises and was also given a rotary exercise from the midline to the left.

One month later, he returned complaining bitterly of the new glass for the right eye. To my astonishment on rechecking, the manifest test showed for this eye a −0.5D. sph. ⌒ +1.25D. cyl. ax. 165°. With this combination normal distance vision was obtained. The findings were checked carefully with the use of homatropine and paredrine, and this prescription was then given for the right eye, with no change in the glass prescription for the left eye. There was considerably diminished internal rotation in the right eye and practically no near point of convergence.

On May 8th, the patient reported blurred vision in the right eye, and the manifest refraction showed a pronounced change since the previous examination, being for this eye −0.75D. sph. ⌒ +2.25D. cyl. ax. 85°. With this prescription a distance vision of 20/20+ was obtained, and at near, with a +2.25D. sph., J1 was obtained.

At this time the right eye was almost fixed in the lateral position, and there was little internal rotation. A heteronymous di-

plopia was present with some suppression of the right eye. The palpebral fissures and the exophthalmometer readings were equal. The patient was advised to have another general neurologic examination and a roentgen study of the orbital regions. The results of these examinations were negative. An exploratory operation for the purpose of doing again the muscle surgery and also checking for a tumor in the region of the lateral rectus of the involved right eye was then advised.

On May 18th, under local anesthesia, the region of the operative scar over the lateral rectus of the right eye was exposed, and it was found that the muscle was surrounded by dense scar tissue of a rather granular type, particularly posteriorly. There was so little elasticity present in the belly of the muscle that it was difficult to cut it free from the globe after placing the recession sutures.

When it was freed, rotation of the globe inward, previously impossible, could be readily accomplished. After the muscle was reattached to the globe posteriorly, several portions of tissue were obtained for biopsy. The mesial rectus, previously operated on, was resected and advanced to the mesial limbus. The conjunctiva was closed. A small piece of rubber tissue was, however, inserted in the depth of the wound around the lateral rectus.

The pathologic report made by Dr. H. R. Mills and Dr. J. N. Patterson, was probable squamous-cell carcinoma, but available tissue showing this pathologic condition was insufficient for positive diagnosis. The wound was reopened on May 26th, and about 1 gm. of pathologic tissue was removed. On microscopic section, this specimen showed squamous-cell carcinoma of about grade III malignancy.

On May 30th, exenteration of the orbit was carried out under pentothal sodium anesthesia. Posteriorly, a large scirrhous mass extended to the periorbita and was firmly fixed to it in the regions of the superior and inferior orbital fissures. The stripping of the periorbita was not easy in these regions, but was accomplished. The lids were removed flush with the orbital margins. The postoperative course was uneventful. Figure 1 shows the completely epithelized wound with scars of irradiated skin lesions, particularly in the right temporal region.

Fig. 1 (Forbes). This photograph shows the completely epithelized wound and also the scars of irradiated skin lesions, particularly in the right temporal region.

Discussion

This case suggests several interesting points. The location for such a tumor was most unusual. The diagnosis of paralysis of the sixth nerve might have been correct, due to the nerve being affected peripherally by a tumor located in the region of the superior orbital fissure. The other nerves in this region should, however, have been involved. Possibly early, the tumor affected mechanically the external rectus far back

and this condition could of course have been overlooked at the time of the original examination.

In addition, the history of skin cancer in multiple form, especially the large one in the right temporal region, was definite. There was no biopsy of these lesions, since it was assumed that they were of the basilar type. The possibility of tumor cells being introduced into the orbit from a very early lesion not recognized at the time of the first muscle surgery must also be considered rather than metastasis.

The refractive changes of the eye on the side of the retrobulbar tumor were really the first concrete signs suggestive of a tumor in this location. Brav and Brav[1] directed attention to the possible diagnostic value of refractive change in selected cases of retrobulbar tumor, and it was mentioned in association with two cases of cavernous hemangioma of the orbit in my report[2] of a series of eight cases of unilateral exophthalmos caused by orbital tumors. In one of these cases there was present squamous-cell carcinoma over the posterior part of the orbital plate with further evidence of the tumor around the optic nerve.

Summary

A case of squamous-cell carcinoma of the orbit is reported.

The outstanding features relating to site, symptoms, diagnosis, and surgical measures in this unusual type of case are discussed.

The significance of refractive change as a possible aid in diagnosis is mentioned.

EXOPHTHALMOS IN NEWBORN DUE TO ORBITAL HEMORRHAGE

A. C. Hilding, M.D.
Duluth, Minnesota

An 11-year-old girl came to the office for refraction recently. She had beautiful and normal eyes and eyelids, and her vision in both eyes was 20/20. Her record contained the following interesting history.

She was born on January 31, 1937, in the position of face presentation. After birth her face was so swollen that the eyes could not be seen. By February 5th the swelling had receded to such an extent that they could be inspected. It was found that there was a marked proptosis of the right eye with limitation of movements.

When I first saw her in consultation, there was beginning ulceration of the upper cornea of the right eye and the lids did not cover the eye. There was a marked protrusion of the globe with every crying effort. There was considerable congestion of the cunjunctivas, and a moist chamber was prepared to protect the eyes. By February 11th all signs of external irritation had subsided but the proptosis still remained. In fact, during the next few days the globe was extruded out of the conjunctival sac beyond the eyelids several times, and enucleation was considered. However, on February 13th the eyelids were stitched together with double sutures over the globe in order to protect it. Spinal and cistern punctures were attempted on February 14th but were unsuccessful.

On February 15th a needle was passed

into the orbit behind the globe and 3 cc. of old blood were aspirated. Aspiration was repeated on the following day, and 1 cc. of blood was removed. After these aspirations the proptosis was reduced by three-fourths. There was still some limitation of movements, however, especially in the upward gaze. Eventually this also became normal.

A diagnosis of orbital hemorrhage due to birth injury was made.

Discussion

Orbital hemorrhage following birth injury seems to be very uncommon. I found only three reports in the literature of unilateral exophthalmos in newborn infants which might be due to hemorrhage. In none of the three was hemorrhage proven.

Velter and Margiat deTrigny[1] reported a case of proptosis, with marked swelling of the eyelids, in 1939. They made a tentative diagnosis of angioma and took a biopsy which proved to be negative.

Windham[2] reported a case, in 1942, in which a sudden exophthalmos developed on the sixth day. He concluded that an orbital tumor was present and planned to operate but the next morning the proptosis had receded 40 percent. He assigned this recession to the effect of the X rays which had been used in taking roentgenograms. He continued treatment with X ray, and 20 days later the eye was normal.

Harley[3] reported a similar case, in 1943, in which the exophthalmos developed the day after delivery and reached such an extent that it measured 17 mm. in the left eye as compared with 6 mm. in the right. The exophthalmos persisted unchanged for about 13 days and then began to get better. It was about gone on the 23rd day, and entirely gone on the 32nd day. Harley concluded that this was probably an orbital hemorrhage and that the effect from the X rays used was debatable.

It is likely that all three of these cases, as well as the one reported here, were due to orbital hemorrhage from birth injury. These cases emphasize the fact that radical measures should be avoided when the eyes of an infant show marked displacement from an unknown cause. Recovery may be complete with simple therapeutic measures and a little patience.

RETINOCHOROIDITIS RADIATA*

Chi Hsin-Hsiang, M.D.
Chengtu, Szechwan, China

From the Rigshospital of Professor Roenne in Copenhagen, T. H. Brown† described an interesting case which he called retinochoroiditis radiata. Both eyes of a man, aged 47 years, showed a similar change of circumpapillary atrophy of the choroid around the normal papilla. From this area atrophic stripes with considerable pigmentation followed the veins to the periphery. The field of vision was slightly contracted and vision was 6/9.

Since a perfect replica of this unique case has been found, it is of interest to describe it.

Case report

History. Patient Wan Pei Wen, a housewife, aged 36 years, complained of redness, pain, and a sense of distention in the left eye for more than three

* From The Eye, Ear, Nose and Throat Hospital.
† Brit. J. Ophth., 21:645, 1937.

weeks. Some impairment of vision was also present. These conditions became progressively worse in spite of treatment including eyedrops and three injections of a sulfonamide. When the pain was severe, it radiated to the corresponding side of the head.

She had never noticed any discomfort in the right eye. Four years ago she had had the same trouble in the left eye which lasted for about three months. At that time she was taken care of by a general practitioner.

The patient was married 17 years ago, had had 11 pregnancies, with two 3-month abortions. The

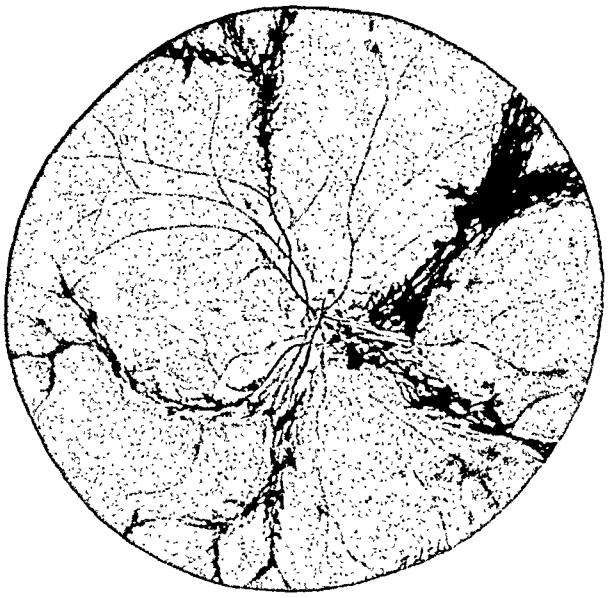

Fig. 1 (Chi Hsin-Hsiang). In the atrophic areas there were irregular-shaped, dark, pigmented patches, scattered evenly on the nasal side. On the temporal side, they were relatively dense at the periphery.

first child, she was told by a doctor, was supposed to have congenital syphilis. A serologic test for syphilis was positive once in 1941, but repeatedly negative for seven times since 1942, after injections of neoarsphenamine. During each period of pregnancy, she received some neoarsphenamine injections which amounted to about 30 altogether. She had no history of chronic cough or hemoptysis, although her father had died of chronic cough and hemoptysis 24 years ago. Her husband had a history of venereal exposure, penile sore, and G.C. urethritis. The woman was admitted to the hospital on July 21, 1947.

Ophthalmic examination. Right eye: The anterior part of the right eye was normal. The disc appeared normal. There was a circumpapillary atrophic area of ½ to 3 disc diameters, the longest diameter being on the nasal side. There were four stripes of atrophic areas radiating out from this circumpapillary atrophic region. These stripes followed the distribution of the main retinal veins. Before these stripes terminated at the equatorial region, they divided and subdivided until they became much narrower in width. The color of the atrophic area was partly grayish with a bluish tint.

In the atrophic areas there were irregular-shaped, dark, pigmented patches, scattered evenly on the nasal side. On the temporal side they were relatively dense at the periphery (fig. 1).

At some regions the pigmented patches ensheathed the retinal veins, so that the vessels appeared black. The retinal arteries were definitely narrower. At certain regions the superior and inferior retinal arteries showed whitish lines running along their sides. The macular region appeared to be normal. Vision was 6/6, J1.

Left eye. The lids were slightly swollen and the palpebral conjunctiva was moderately congested. There was a tender nodule (episcleritis) 1.5 by 1 cm. in size at the 3-o'clock position of the limbal area, with deep injection which did not fade after using adrenalin. There were numerous fine deposits on the posterior surface of the cornea, chiefly located on the temporal side. The anterior chamber was slightly deeper than on the right side. There was blurring of the iris pattern. The pupil dilated well under atropine. Fine whitish and brownish spots were found on the anterior lens capsule. Intraocular pressure was normal.

The general appearance of the fundus was the same as in the right eye except that the circumpapillary area of atrophy was narrower and the stripes which ran from the papilla to the periphery, following the veins, were thinner. As the eye was irritated by the scleritis, a picture could not be taken of the fundus. Vision was 6/30, J3.

Visual fields. The right eye showed a slight concentric contraction and a horizontal enlargement of the blindspot. The left eye showed more concentric contraction but did not show an enlargement of the blindspot.

Laboratory findings. Wassermann, Kahn, and Ring tests were negative. Tuberculin test was positive to 1/1000 mg. Fluoroscopy of the chest was normal.

Treatment of the left eye consisted of atropine dionine as eye drops. The episcleritis was treated by rubbing a copper sulphate stick on it.

Course. On discharge, August 6, 1947, the episcleral nodule had completely disappeared. There was no photophobia or lacrimation. Vision was 6/7.5.

Comment. The change of the fundus was apparently an old one, since the patient and all her present complaints were due to the episcleritis. In these factors this case resembles that reported by Brown, as it also does in the good vision and the change of the field. Another similarity is that the disease apparently originates on the retinal veins because all the bands of choroidal and retinal change follow the veins and their distributions.

The retina shows the most conspicuous changes because the pigmented deposits are lying in its innermost layers, covering many parts of the retinal vessels and, in places, enveloping the retinal veins in black sheaths. The white part of the circum-

papillary atrophy and the stripes are due to the atrophy of the pigment epithelium and of the choroid.

Discussion

In agreement with Brown, we consider the origin of this disease to be an inflammation of the veins. The arteries in our case also showed considerable changes by their attenuation and by their accompanying sheaths, that means that there was once an arteritis. Without doubt, however, the change of the veins is more marked and important and the acute stage of this whole fundus picture was apparently once a widespread periphlebitis.

A difference between Brown's case and the one herein presented is the etiologic factor. In Brown's case tuberculosis was apparently the etiologic factor, while in our case there was very little evidence of tuberculosis but the patient had had syphilis.

The explanation of this characteristic and unusual picture of the fundus is difficult if we consider the etiology. Periphlebitis, as a rule, is of tuberculous origin but has a quite different clinical picture. Usually, it is on the periphery. It also has a tendency to recur and finally leads to vitreous hemorrhages (Eales's disease) and retinitis proliferans. A third difference is that tuberculous periphlebitis does not lead to any pigmentation of the retina. In arrested cases of periphlebitis retinae we have newly formed veins, with fine white membranes of connective tissue following the veins and crossing the newly formed loops.

Periphlebitis retinae occurs near the papilla but rarely. Apparently it causes the destruction of the nerve-fiber layer of the retina with corresponding defect in the visual field. If tuberculosis was the etiologic factor in Brown's case, it produced an unusual condition in that the periphlebitis started near the papilla, following all the veins and producing much pigmentation.

On the other hand, syphilis, the etiologic factor in our case, is known to be a cause of arteritis of the retina and to produce pigmented sheaths on the peripheral arteries of the retina. Periphlebitis apparently does not play any role in the pathology of syphilitic diseases. In our case, we have only a slight involvement of the arteries, but very marked pigmentation along the veins. One is tempted to deny syphilis because the veins are involved in such a degree, and yet the pigmentation makes the syphilitic origin very likely.

Retinochoroiditis radiata presents not only a marked and typical appearance of the features: (1) The acute stage probably does not cause much visual impairment. (2) It does not cause much impairment of the whole retina since vision is good.

A CASE OF MULTIPLE NEUROFIBROMATOSIS WITH SOME UNUSUAL FEATURES*

Elliot A. Wallach, M.D.
Richmond Heights, Missouri

The following case of neurofibromatosis is presented because of the unusual distribution of the lesions on the palms of the hands, the scalp, and the mucocutaneous borders of the upper and lower eyelids, where they are responsible for a recurrent trichiasis. In addition, in this case there is a clear-cut history of the existence of the same condition in three successive generations, both the father and son of this patient being similarly afflicted. A 3-year-old grandson has developed café au lait spots, a precursor of the condition.

Case report

History. B. G., a 58-year-old white man, was hospitalized in July, 1941, with chronic, far-advanced pulmonary tuberculosis. He stated that he first noticed multiple small

*From the Department of Medicine and Surgery, Veterans Administration, Oteen, North Carolina.

Fig. 1 (Wallach). Small, discrete tumors are visible on forehead, face, and eyelids where they cause a turning-in of the lashes.

tumors on the chest in 1918 when he was about 30 years of age. Since 1925, when small tumor masses appeared on each eyelid, he has had to have his lashes plucked out because, as he put it, "they turn in and rub against my eyes."

On physical examination his entire body was found to be covered with multiple small tumors located, in general, between the skin and subcutaneous tissue. Many of the lesions were pedunculated, soft, pliable, and moderately tender to pressure. An actual count of the number of the masses in the middle of the back averaged between 25 and 40 per square inch, with diameters varying from 1 mm. to 1.5 cm. The majority of the larger lesions were pedunculated and most of them had a definite ring of tissue at the base through which the tumor mass protruded. Some could be felt better than seen and presented themselves to the palpating finger as soft masses beneath the skin, not readily visible. In general they were of a dull red color which was not continuous with the hue of the surrounding skin. No areolas were present.

The general distribution defied accurate description. Although densest over the lower lumbar region and lower abdomen, they also extended from well into the scalp to the face where they invaded the eyelids (fig. 1) causing a turning in of the lashes.

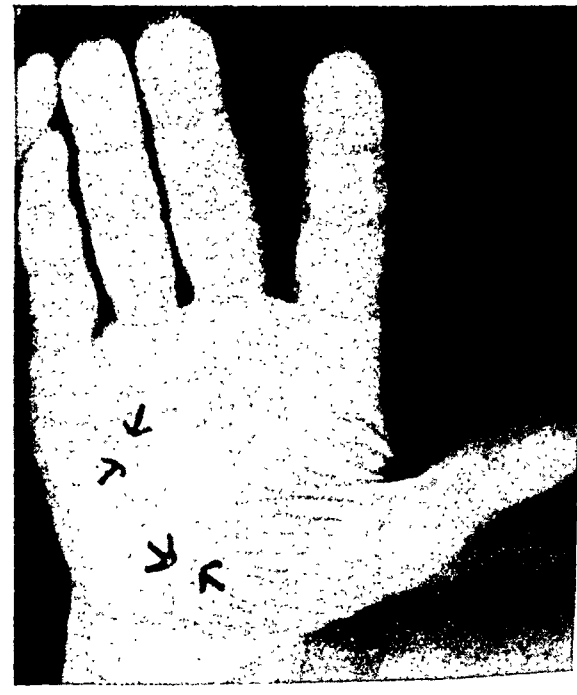

Fig. 2 (Wallach). Multiple, discrete pinhead-sized to pea-sized lesions on inner aspect of both forearms and palms.

At this site, the lesions were smaller and firmer than elsewhere on the body. From the face they extended down the neck to the arms, forearms, and into the palms (fig. 2). The upper chest and sternal area were densely covered with the masses, and the penis and scrotal sac were also involved. The lower extremities were not heavily invaded, the number of lesions decreasing markedly from below the hips to the upper thighs. Those on the legs and thighs were small and slightly raised. Light brown pigmented areas (café au lait) were noted on the thighs, these areas varying in size and shape. The patient stated that he noticed a progressive increase in the number and size of the lesions.

A neuropsychiatric examination revealed the patient to be mentally clear and adequate.

X-ray examination of the spine showed narrowing of the anterior portion of the interspaces of the lower dorsal vertebras due to pressure. X-ray examination of the lungs, bones, and skull revealed no abnormalities.

Laboratory tests. The blood Wasserman was negative. Calcium-phosphorus and phosphatase levels were normal. Examination of the blood was normal.

Comment

There have been cases reported in the literature of von Recklinghausen's disease involving the eyelids. These articles, however, as well as the standard texts on ophthalmology mention only the single, large, soft type of tumor, not involving the lashes. These tumors were removed en masse surgically. The lesions on the eyelids referred to in this article are the small, multiple, hard type of neurofibromas associated with a widespread distribution of the disease. I have been unable to find a report of this type of lesion associated with a trichiasis. Palmar and scalp involvement in multiple neurofibromatosis is also very rare, but has been reported.[1]

Our patient was one of a family in which similar lesions were present in three consecutive generations and there is a strong possibility that a grandson (fourth generation) will develop neurofibromatosis, since he already shows the café au lait spots, which are generally considered a precursor of the condition. Frank[2] has reported the familial incidence of von Recklinghausen's disease traced through five generations.

SOCIETY PROCEEDINGS

Edited by DONALD J. LYLE, M.D.

MEMPHIS SOCIETY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

January 13, 1948

HERNIATION OF THE VITREOUS

DR. CHARLES M. KING presented a case of herniation of the vitreous following a simple intracapsular extraction of a nuclear cataract in Mrs. W. A. C., a white woman, aged 60 years. Removal of the prolapsed vitreous from the pupillary space was described.

On July 9, 1947, a simple intracapsular extraction with a peripheral iridotomy was done for nuclear cataract. Two McLean sutures were used. No vitreous loss or other complications at the time of operation were encountered. On the night following surgery the patient had pain in the eye and, on examination the next morning, there was a moderate hyphemia present. The iris was visible through the blood. On the fifth postoperative day, there occurred another moderate hemorrhage into the anterior chamber. The subsequent blood clot was slowly absorbed.

On August 1, 1947, a sacculated herniation of the vitreous through the pupil was found, and there were blood pigments and small bits of clot on the face of the vitreous. This prolapse closely resembled a mushroom in its shape, the contracted pupil causing a narrow pedicle to be present. Miotics did not effect any change in the size, shape, or appearance of the herniation.

On August 20, 1947, a Wheeler knife was introduced into the anterior chamber and the sacculated vitreous prolapse was cut on the plane of the iris. A 2-cc. hypodermic syringe with a 22-gauge needle, bevel up, was introduced into the chamber and an attempt was made to withdraw vitreous through the needle. A very small amount went into the cannula of the needle. With suction maintained, the needle was withdrawn and a long string of discolored vitreous trailed along in its path. This string was grasped with forceps and all the prolapsed vitreous was slowly pulled out of the anterior chamber. The pupillary area was left clear.

On September 23, 1947, corrected vision in the eye was 20/20—2, J1. There were many fine vitreous opacities scattered over the vitreous proper and at times the patient's vision was temporarily disturbed.

This presentation was made because not much has been reported locally concerning this type of vitreous herniation following intracapsular cataract extraction. Perhaps good fortune was smiling upon the surgeon in this instance. The desired results were obtained and no special instruments were required for the procedure.

ALLERGIC REACTION OF PREVIOUSLY SENSITIZED EYE TO PARENTERAL PENICILLIN

DR. JAMES E. WILSON reported that Dr. R. H. M. had a conjunctivitis of the left eye on September 16, 1946, which was treated with penicillin. This produced a reaction of the conjunctiva and skin of the lids so that penicillin was discontinued. No penicillin was ever used in the right eye.

On December 1, 1947, he began receiving parenteral penicillin for a urinary infection. No penicillin had been used in or about either eye since September, 1946. About eight hours after parenteral administration was begun, the conjunctiva of the left eye and the skin of the lids became red and swollen. The skin was rough and the reaction extended down onto the cheek.

Pyrabenzamine (50 mg., 3 times daily),

cold boric compresses, and discontinuance of the penicillin injections completely cleared the eye reaction in 24 hours.

The right eye remained normal throughout. The only general symptom was itching of the skin of the legs.

Mr. R. L. S., Jr., Dr. Wilson's second patient, had an acute conjunctivitis of the left eye on December 1, 1946, and this eye only was treated with penicillin with prompt recovery. On February 5, 1947, he was hospitalized for a severe respiratory infection and received parenteral penicillin.

Within 10 hours he had a severe swelling and redness of the conjunctiva of his left eye. The skin of the lids became rough, red, and swollen even down onto the cheek. The right eye remained normal.

After 24 hours he developed a rash over most of his body, worse on the legs, accompanied by intense itching. He was treated with Benadryl, forced fluids, discontinuance of penicillin, and sodium thiosulphate. In 15 hours the left eye had returned to normal, but the general reaction was longer in clearing.

Value of Berman locator

Dr. James E. Wilson said that Mr. G. B.'s right eye was injured on July 14, 1947, by entry of a foreign body received while hammering on an iron fence.

The wound of entrance was 3-mm. long at the 5:30-o'clock position, one half in the cornea and one half in the sclera. The anterior chamber was shallow. One small linear hemorrhage in the vitreous was seen at the upper nasal position. The lens did not appear to be injured. X-ray localization showed a 1 by 2 by 3-mm. foreign body of metallic density well back and in the upper nasal position. According to the localization it was situated in the sclera, or very close to it, either inside or outside the globe.

Protruding iris was excised and the wound was closed with three 6-0 black silk sutures. The internal rectus was exposed. The Berman locator showed the site of the foreign body to be 6 mm. posterior to the muscle attachment and beneath the middle of the muscle. The muscle was detached and the locator, applied directly to the sclera, indicated the point for posterior-route removal. A mattress suture was placed and diathermy punctures were made. Next an incision with the keratome was made down to but not through the choroid. The foreign body came through with the first application of the hand magnet. The sutures were tied and no vitreous was lost. Three weeks after the injury the vision was 20/20 J1, uncorrected.

The Berman locator is always a help in localizing intraocular foreign bodies and is valuable in borderline cases, such as the one reported here.

Dr. Wilson's fourth case was that of Mr. L. T. K. who, while hammering on a chisel against a transmission on December 4, 1947, felt something strike his left eye causing immediate pain.

Examination showed a vertical 2-mm. wound at the nasal limbus with a small peripheral opening in the iris. The anterior chamber was full and no blood was seen. With the ophthalmoscope a small, dark-gray mass was seen in the upper nasal quadrant just posterior to where the foreign body entered. Fundus findings were otherwise negative. Vision was 20/20.

X-ray localization showed a 1 by 2 by 3-mm. foreign body near the sclera, about the position of inferior rectus insertion.

At operation, exposure was made over the insertion of the inferior rectus. The Berman locator indicated the ideal place for posterior-route extraction. The tendon and muscle fibers of the inferior rectus insertion were separated meridionally. The suture, diathermy punctures, and scleral incision were the same as in the first case. The foreign body came out with the first application of the magnet. No vitreous was lost.

The precise localization with the Berman instrument made it unnecessary to detach

the inferior rectus. On December 9, five days later, the vision was 20/20, uncorrected.

Lymphatic leukemia with lacrimal gland involvement

Dr. James E. Wilson reported that Dr. W. L. B., in September, 1946, had elevation of temperature and general malaise. White blood count was about 64,000 and, on the basis of blood tests, a diagnosis of lymphatic leukemia was made. In November, 1946, he had radioactive gold with prompt reduction of the W.B.C. to 10,000. He had a further reduction within 2 to 3 months to about 4,500 where it has remained since.

About February, 1947, he had enlargement of the spleen and axillary glands. These responded promptly to X-ray radiation. These glands were affected again in May and August when they were treated with X-ray radiation. In December, 1947, the same glands plus the inguinal and glands of the chest were involved. He received radiation treatments for these.

On November 10, 1947, he was examined and found to have enlarged glands in the lacrimal area, extending medially about 4 centimeters. The swelling was so great that the upper lids were pushed down, interfering with vision. Upon eversion of the lids, pinkish dusky masses were seen filling the upper fornices and extending from the lacrimal area to beyond the midline above. The masses extended subconjunctivally down onto the globe. The enlargements were symmetrical.

At operation on November 10, 1947, the upper lids were retracted upward through a conjunctival incision. The masses were isolated and removed. The mass on the right extended farther back into the orbit involving the superior oblique from which it was dissected. A small amount of the tumor in the area of each lacrimal gland was left to prevent subsequent dryness. Healing was uneventful and the patient left the hospital in four days. To date, December 10, 1947, there has been no return of the masses or enlargement of the part which was left.

Pathologic report. Gross appearance: Specimen consists of five ovoid pieces of pale-pink tissue, the largest of which measures 2.5 cm. in diameter. This tissue is covered by a thin capsule. On section, the parenchyma appears homogeneous throughout. Some specimens are not as well defined as the one just described. These contain a larger amount of fibrous tissue.

Microscopic diagnosis. Lymphatic infiltration of lacrimal gland, compatible with lymphatic leukemia. Mikulicz's disease cannot be excluded.

Resection-recession for external rectus paralysis

Dr. J. Wesley McKinney reported the case of Mrs. J. L., aged 42 years, whose left eye had been crossed all of her life. Her father had right abducens palsy and her daughter had bilateral abducens palsy from birth. Examination revealed an esotropia of 13 degrees. There was diplopia if she looked straight ahead. Therefore, she habitually carried her head turned to the right. There was a paralysis of the left external rectus. The left eye failed to rotate to the midline by 16 degrees. This corresponded exactly with the binocular field which showed the diplopia to be overcome beyond 16 degrees, eyes to the right. At operation, the left internus was recessed 5 mm. and the left externus resected 6 mm.

Six weeks later there was binocular single vision from 16-degrees left to 20-degrees right. The patient was entirely comfortable and no longer held her head rotated to the right side. With the red glass there was 6-degrees esophoria with the right eye fixating; and 4-degrees with the left eye fixating for distance. There was orthophoria for near. The convergence near point was 6 cm.

Muscle transplantation for external rectus paralysis

Dr. J. Wesley McKinney reported the case of R. L., aged 11 years, who was first

seen December 6, 1944. Both eyes had been turned in since birth. The grandfather had right abducens palsy and the mother had left abducens palsy.

Examination revealed a bilateral paralysis of the external recti with much secondary contracture of the internal recti. Neither eye could be rotated to the midline. Fixation alternated. With the right eye fixating, the esotropia measured 40 to 45 degrees; with the left eye fixating, the esotropia measured 35 degrees.

At operation, both internal recti were recessed, both external recti were resected, and the lateral halves of both superior and inferior recti were transplanted to their respective external recti.

The result was over correction of 15 degrees with the right eye fixating and 10 degrees with the left eye fixating. The actual exotropia was less than these figures would indicate. There was a positive angle kappa of 5 degrees for the right eye and 10 degrees for the left. The left eye was reoperated upon, the external rectus being set back 5 mm.

The final cosmetic result was good. External rotation was 30 degrees for the right eye, and 35 degrees for the left.

Melanoma of thf choroid

Dr. R. O. Rychener reported a case and exhibited the pathologic section of melanoma of the choroid.

Mr. J. G. P., aged 45 years, was seen on July 29, 1947, in consultation with Dr. Ralph W. Danielson at Denver, Colorado. One year previously the patient had been refracted with normal vision in each eye and no fundus lesion was noticed on ophthalmoscopic examination. For the past two months some visual diminution had been noticed in the left eye and, upon recent examination, what appeared to be a neoplasm of the choroid in the left fundus, temporal to the macula, was observed by Dr. Danielson and his associate. Upon examination here the media were clear. At the temporal and superior border at the left macula was a dome-shaped grayish brown mass about 2 disc diameters in diameter, elevated at its greatest height 6 disc diameters above the level of the disc. Flakes of brown pigment lay behind the retinal vessels on the temporal border. On the nasal border appeared to be a small retinal cyst flecked with pigment, overriding the mass like a bulla on the cornea. Transillumination was unsatisfactory because of the location of the lesion at the posterior pole, but at times a small shadow seemed to be present. The diagnosis established in Denver was confirmed and further consultation advised.

The patient was later seen at a well-known clinic in the north where the diagnosis of choroidal exudate was made and expectant treatment was advised. In December he was seen at another clinic in the east where diagnosis of intraocular sarcoma was made and enucleation advised. This was done and pathologic section showed a grade-2 melanosarcoma of the choroid, involving the posterior ciliary nerve.

Intraocular foreign body

Dr. Richard A. Miller reported Mr. H.I.O., aged 37 years, who was seen on February 16, 1948. The following history was given.

In the autumn of 1946, while hammering on a piece of steel, a foreign body struck him in the right eye. He immediately reported to a doctor who examined the eye and told the patient that there was no intraocular foreign body, that he was evidently struck a glancing blow by the flying material which did not penetrate the globe.

In the subsequent few weeks the vision in this eye began to fail and four months later he consulted an ophthalmologist who took X-ray films, found an intraocular foreign body, and so informed the patient. He also advised the patient to leave the eye alone unless it became painful.

When seen by me, the patient complained of dull aching pain in the right eye for the previous week. Examination showed vision

to be: R.E., light perception and projection; L.E., 20/20, J1. Examination of the right eye showed mild ciliary injection and an old perforating scar just lateral to the center of the cornea. The anterior chamber was shallow, the pupil 4 mm. in diameter and sluggish in its reaction to light. The lens was opaque and, in its lower portion just beneath the capsule, there was a brown foreign body approximately 2 by 4 mm. in diameter. There was no fundus reflex. The intraocular pressure in the right eye was 40 mm. Hg (Schiøtz); left eye, 20 mm.

The next day, under local anesthesia, an extracapsular extraction of the lens was performed through a round pupil, delivering the foreign body with the lens nucleus. The patient has made an uneventful recovery and on March 8, 1948, the vision in the right eye was improved to 20/40 with a +11D. sph. ⊃ +1.0D. cyl. ax. 180°.

Krukenberg's spindle

Dr. Philip Meriwether Lewis presented a white woman, aged 27 years, with typical Krukenberg's spindles.

The patient complained that her eyes ached and tired easily. She was quite obese and took thyroid extract regularly. The condition was discovered on making a routine examination along with cycloplegic refraction. The eyes were normal except for the brown pigment deposits on the corneal endothelium. Most of the pigment spots were arranged to form vertical spindles, centrally located. Each measured about 1.5 mm., horizontally, and 5 mm., vertically. There was a diffuse scattering of pigment over a broad area of the cornea in addition to the denser clumping which formed the spindles. Vision was 20/25 in each eye.

Comment. Duke-Elder stated in his text (volume 2, page 2036) that some 70 cases were in the literature. The condition was not nearly so rare as the small number of cases indicated. Many cases were not reported when diagnosed and many were overlooked. The spindles were first described by Krukenberg in 1899. The chief interest in them concerned the etiology. It was the consensus of opinion that the condition was not congenital, but was due to an atrophic process in which uveal pigment was deposited on the endothelium of the cornea in this unusual arrangement.

Simple versus combined cataract extraction

Dr. Philip Meriwether Lewis presented two patients upon whom simple intracapsular cataract extractions had been performed on both eyes.

Case 1. Mr. A. L. W., a white man, aged 44 years, was first seen in June, 1946, with the complaint of failing vision for four years. Examination showed a clouding in the posterior cortex of both lenses most marked in the left eye. Iridodonesis was present in both eyes, but the lenses were apparently not subluxated.

Vision was: O.D., 20/200; O.S., 5/200. With a −2.25D. sph., O.D., 20/40; and with a −4.0D. sph., O.S., 20/200. A plus 1.75D. addition gave J4 and J14, respectively. These glasses enabled the patient to carry on his work as an executive for slightly more than a year.

Complete physical and laboratory studies by his physician were entirely negative. In July, 1947, vision could not be improved beyond: O.D., 20/100; O.S., 8/200; J12 was the smallest type he could read.

On August 21st, a simple intracapsular extraction with peripheral iridotomy was performed on his left eye. Four days later the same procedure was done on the right eye. There were no postoperative complications. Eight weeks after operation final refraction was done. O.D., with a +13.25D. sph. ⊃ +0.5D. cyl. ax. 120° = 20/20+; O.S., +12.75D. sph., ⊃ +0.5D. cyl. ax. 135° = 20/20+. With both eyes, he read the 20/15 line completely. With a plus 2.5D. addition, he read J1 at from 13 to 20 inches. He was able to use his eyes together perfectly.

Case 2. Mr. M. L. W., a white man, aged 52 years, was seen first in February, 1946, with the complaint of failing vision for one year. Examination showed posterior cortical cataracts of both eyes, but vision was 20/40 in each eye. With a +2.25D. sph., vision was increased to 20/30, J3.

A general examination by his physician was negative. He was able to do his work as a metal plater until August, 1947, when his vision had become too poor (20/100, J10) to continue.

On August 26, 1947, a simple intracapsular extraction was performed on his right eye and three days later the same on his left eye. There were no postoperative complications. Nine weeks after operation he was refracted. Vision was: O.D., with a +11.25D. sph. ⊂ +1.25D. cyl. ax. 115° = 20/20; O.S., with a +11.25D. sph. ⊂ +1.0D. cyl. ax. 80° = 20/20. With a plus 2.5D. addition he read J1 at from 14 to 20 inches. He was able to resume his work almost immediately.

Comment: These patients were presented for two reasons.

1. I have in the past presented numerous cases that showed undesirable results from numerous and varied complications following cataract extractions. It seemed permissible to show a few good results occasionally.

2. To promote a discussion among the members as to the selection of cases for extraction without iridectomy. A number of years ago I did a much higher percentage of simple extractions than at present. Various complications led to the belief that they should be done only in relatively young patients who intend to lead an active and productive life for a considerable span of years after operation. In the majority of cases the combined extraction was safer.

DR. EDWIN B. DUNPHY, *presiding*

IMMUNOLOGIC REACTIONS OF HUMAN SERUM GAMMA GLOBULIN IN HERPES SIMPLEX AND EPIDEMIC KERATOCONJUNCTIVITIS.

DR. HENRY F. ALLEN of Boston presented this subject. He said that experiments performed by J. T. Heyl, H. F. Allen, and F. S. Cheever have demonstrated in human serum gamma globulin neutralizing antibodies against the virus of herpes simplex.

The titer of this antibody was of the same order of magnitude in separate samples of serum gamma globulin obtained from the pooled serum of donors from different sections of the United States, being approximately 15 times the titer of human anti-herpes immune serum.

Passive protection tests in mice showed positive protection when a single large dose of globulin was given intraperitoneally up to 48 hours after intracerebral injection of a lethal dose of herpes virus. Since these experiments were not carried to the point where this protective effect disappeared entirely, the passive protection tests must be considered as having only preliminary significance.

The same technique employed in carefully controlled experiments failed to demonstrate either a neutralizing or a protective effect of human serum gamma globulin against the virus of epidemic keratoconjunctivitis. It was, therefore, concluded that these two viruses are immunologically distinct from each other.

Discussion. Dr. Frederick H. Verhoeff asked Dr. Allen to explain the mode of attack of herpes virus—whether the immunity is low between attacks and is boosted by each individual attack, and whether the virus is always present.

Dr. Allen replied that Burnet and others

have demonstrated the absence of antibodies in the serum of individuals prior to an initial attack of herpes simplex and the development of circulating antibodies during and after the primary attack. A demonstrable titer then remains until the end of that individual's life. It is probable that the antibody level decreases between attacks until some suitable stimulus, most frequently generalized fever or local tissue injury, predisposes to a recurrence which stimulates the formation of additional antibody. The virus is presumed to be present, either in active or in latent form, at all times after it has once gained entry to the body at the time of the initial attack. The exact role of circulating antibody in the mechanism of immunity to herpes simplex in the human body is not clear.

Dr. Verhoeff then asked Dr. Allen whether he had any explanation for the results of other workers who concluded that the virus of herpes simplex and epidemic keratoconjunctivitis were immunologically related and probably of the same genus. Dr. Allen replied that the present studies did not have any bearing upon the results obtained by these workers but that the conclusions drawn from the two sets of studies were at variance.

Dr. David Cogan pointed out that two of the stimuli for Dr. Allen's study were (1) a case of dendritic keratitis with an apparently dramatic cure by systemic use of gamma globulin and (2) the hope of obtaining therapeutic benefit from local use of gamma globulin in the high concentrations that would thereby be available. Dr. Cogan asked Dr. Allen if he had any explanation for the predilection of herpes for the cornea.

Dr. Allen said that therapeutic benefit from human serum gamma globulin could not be anticipated on theoretical grounds, since the intracellular location of the virus renders it inaccessible to circulating or locally applied antibody. Clinical trials in cases of dendritic keratitis failed to show any response to local or systemic administration of gamma globulin. Dr. Allen stated that he was unable to offer any explanation of the predilection of herpes simplex for the cornea; he stated that the virus has been shown experimentally to invade tissues derived from all three of the embryonic layers. He also stated that one of the striking properties of the herpes virus is the ease with which it is oxidized. Application of this principle is seen in local treatment of dendritic keratitis by scrubbing the corneal epithelium with strong alcoholic solution of iodine, as described in detail by Dr. Trygve Gundersen.

In reply to a question by Dr. James Regan, Dr. Allen stated that he had not attempted iontophoresis with human gamma globulin in the conjunctival sac.

Dr. Trygve Gundersen said that he had had somewhat the same experiences with the protective properties of immune blood in herpes simplex; that he had given rabbits their own weight in rabbit convalescent serum and found them just as susceptible to inoculation of the cornea with the virus of herpes simplex as ever.

Use of buccal mucosa in restoration of the orbital socket.

The above was the subject of the paper of the evening by Dr. James N. Greear, Jr., Washington, D.C. This paper was published in full in the Journal, 31:445-453 (April) 1948.

Discussion. Dr. Bradford Cannon, opening the discussion, mentioned that military patients presented a real challenge, because they were usually more demanding of the surgeon's services in the reconstructive phases of their care than civilians. The accidental injuries of a civilian were usually of his own doing or fault, while the men in the armed services did not ask to be in the service and be wounded, and therefore feel that they deserve everything that they can get.

He reëmphasized Dr. Greear's statements in regard to the importance and value of

mucous membrane in socket construction, inasmuch as in substitution one necessarily has to find tissues which resemble as nearly as possible the original tissues. He said Dr. Greear's demonstration of the possibilities of its use and the amount available from the mouth has been a tremendous boon to this phase of surgery.

Dr. Cannon thought that the reasons for the superiority of mucous membrane in socket repair were analogous to the use of the skin from the base of the neck in eyelid repair in preference to skin from the extremities and back of the ear. Not only does the skin of the neck match that of the lid better, but it is underlaid by a thin sheet of muscle which is analogous to the muscles which play upon the skin of the face and eyelids and make possible facial expression. The skin of the extremities is less suitable because it has deep fascia between the skin and muscles, and the skin behind the ear is less suitable because it is underlaid by cartilage and bone. He thought that in socket repair the mucous membrane in the mouth, played upon by delicate muscles in the cheek, is more suitable because it does not tend to shrink and is accustomed to lie adjacent to delicate muscles.

Dr. Cannon reëmphasized Dr. Greear's point that, in successful reparative surgery, it is of the utmost importance to remove the scars that are caused by the deep and penetrating wounds that are usually incurred in war. He challenged Dr. Wheeler's ability to use a graft of epidermis only, as mentioned by Dr. Greear. In his experience and that of others the removing of epidermis only from skin surfaces is possible, but they found that such a transplant falls apart very quickly.

The integrity of a sheet of skin depends on the presence of a dermal layer underneath. Microscopic sections of Thirsch grafts demonstrate that a thin layer of dermis is present. In regard to Dr. Greear's comments on the gauze used he felt that vaseline gauze was not good because it failed to absorb secretions, thus increasing maceration, and so he preferred either coated gauze or one impregnated with material to make it more absorptive.

In the general discussion that followed, Dr. Hanford Auten asked about the anesthesia used, the problem of maintenance of an airway while taking oxygen, and the after care of the mouth.

Dr. Hugh Donahue inquired why Dr. Greear does not undermine the edges of the buccal mucosa. Dr. Garrett Sullivan asked Dr. Greear to explain his method of exposure when cutting the graft.

Dr. Greear, in reply, said that he preferred general anesthesia with the mouth tightly packed to prevent aspiration of blood. Physiologic saline solution was injected beneath the mucous membrane to facilitate the cutting of the graft. This latter procedure was unnecessary if the operation was carried out under local anesthesia.

It was more desirable not to undermine the edges of the mucosa in order that the wound edges may be accurately approximated and no dead space created. The healing was by primary intention and there was no deformity afterward. The after care of the mouth consisted of washing the mouth thoroughly after eating with some mild antiseptic solution such as Dobell's. He stated that he had never had an infection of the mucosal wound. This was attributed to the fact that no patient was operated upon until the mouth, nose, and throat were free from infection.

To keep the mouth open he used towel clamps, one just above and one just below the angle of the mouth on the side from which the graft was to be taken. An excellent exposure could be obtained by putting these on the stretch and making a little pressure from without.

CLINICAL PROGRAM

(Presented by the staff of the Illinois Eye and Ear Infirmary)

RETROLENTAL FIBROPLASIA WITH GLAUCOMA

DR. WILLIAM HIRST presented an 8½-months-old girl who was first seen at the Infirmary in October, 1946. The child was one of twins who were born after a gestation period of 7½ months and weighed 3½ pounds at birth. The twin brother has developed normally in every respect and has had no visual difficulty to date.

The mother first noticed a "whitish appearance" of the pupillary areas shortly before bringing the child to the clinic. She had also noted that the eyes fixed poorly and moved irregularly from side to side.

Examination revealed pendular nystagmoid movements of both eyes, very shallow anterior chambers, and yellowish-gray opacities occupying the pupillary areas bilaterally. Ophthalmoscopically, the grayish opacities were found to lie directly posterior to the lenses; normal red reflexes were entirely absent; the irides were dome shaped and at this time a diagnosis of bilateral retrolental fibroplasia was made. Intraocular pressure was: R.E., 27 mm. Hg; L.E., 46 mm. Hg (Schiøtz).

General physical examination showed a rather large head, with prominent frontal bosses and some flattening of the parietal areas, but otherwise was essentially negative.

Three months after the first examination tensions were taken under general anesthesia and were found to be: R.E., 26 mm. Hg; L.E., 39 mm. An iridencleisis was then performed on the left eye. The postoperative course was uneventful. One month following surgery the left eye was completely pale and the tactile tension bilaterally was considered normal. Six months postoperatively, the tension in the unoperated right eye had risen for the first time to 39 mm. Hg; L.E., 25 mm. Both anterior chambers were quite shallow and no fundus reflexes could be seen. No filtering bleb was present in the left eye.

Gonioscopy on November 12, 1947, revealed the following: R.E., shallow angle visible only to the first portion of the trabecula; an anomalous vessel at the 9-o'clock position; a dome-shaped iris. L.E., no angle details were visible temporally; nasally and below, visibility to the midportion of the trabecula was obtained. The temporal pillar of the iris was incarcerated at the 12:30-o'clock position. Many radial iris vessels were seen peripherally. Intraocular pressure at that time was: R.E., 43 mm. Hg; L.E., 32 mm.

Retrolental fibroplasia is frequently associated with microphthalmos, dome-shaped irides, very shallow anterior chambers, and is thus prone to develop glaucoma. No evidence of embryonal tissue was found in the chamber angle of either eye in this case. Therefore, from the gonioscopic findings it is felt that the glaucoma present is due to a narrow-angle mechanism rather than obstruction of the angle by embryonic mesodermal tissue. Relief of intraocular pressure in the left eye was obtained by an iridencleisis over a period of 11 months. The absence of a filtering bleb probably means that the iridencleisis is functioning as an iridectomy in the presence of a narrow-angle glaucoma.

No satisfactory form of therapy has been found for the condition known as retrolental fibroplasia. This case illustrates temporary amelioration by an iridencleisis of the increased intraocular pressure in one eye and is presented as a therapeutic problem. The iris vessels seen peripherally in the angles of these eyes may represent another manifestation of an abnormal persistence of

blood vessels, after which fibroblastic proliferation occurs.

Recovery after occlusion of central retinal artery

Dr. John M. Thompson presented a white man, aged 58 years, who was seen at the Infirmary complaining of suddenly noting a curtain of foggy vision over the right eye 15 minutes previously.

Examination revealed vision to be: R.E., 20/40—2; L.E., 20/20. However, the letters of the test chart could be seen only momentarily with the right eye and then faded completely. Visual field was markedly constricted. Tension was 25 mm. Hg (Schiøtz); blood pressure, 195/110 mm. Hg. Ophthalmoscopically, the right fundus showed one-third disc diameter of interruption of the central retinal artery with blanching of the peripheral vessels and complete obliteration of the nasal radicals. There was beading and generalized fragmentation of both the arterial and venous trees. The retina was pale, although not milky white. The left eye showed a normal fundus.

A diagnosis of occlusion of the central retinal artery was made, and treatment was instituted within 25 minutes of onset of symptoms. It consisted of inhalation of amyl nitrite, massage of the globe, retrobulbar injection of 1 cc. of 2-percent novocaine, and paracentesis. Sodium nitrite was then administered and the patient was put to bed. Tobacco was forbidden. In less than one hour blood flowed smoothly through the involved retinal vessels. The patient was allowed to become ambulatory after 24 hours of bed rest.

Vision of the right eye improved to 20/20; fields were normal. There were no residual findings other than atheroma of the inferior temporal artery. During the six months since this episode there have been no recurrences. In view of the atheromatous changes visible after the acute occlusion had been relieved and the success of vasodilator therapy, it was thought that an angiospastic process superimposed on an organic narrowing of the central retinal artery was the pathologic basis of this occlusion rather than a thrombosis or embolic phenomenon.

Congenital ectropion of pigment border of iris

Dr. Manuel L. Stillerman presented a white girl aged 5 years, first seen at the Infirmary on July 28, 1947, because of pain in the region of the right eye for six months. She had been using "drops" prescribed by an ophthalmologist for seven weeks prior to admission. The child's mother stated that the right eye had always been larger than the left and that the pupil had always looked "peculiar."

When first seen, tension in the right eye was 50 mm. Hg (Schiøtz). Vision was 20/100 (illiterate) and could not be improved by manifest refraction. There was mild puffiness of the lids. The right eye was more prominent than the left by 25 mm. (Hertel). The cornea measured 12 by 12 mm. and the anterior chamber was slightly deep.

The iris was tan in color and the stroma was thinner than in the left eye, but no true atrophy of Fuchs's crypts was noted. The pigment layer of the iris was advanced over the pupillary margin onto the anterior surface of the iris in apronlike fashion, with the appearance of a pseudocoloboma.

The pigment layer was dark brown, with velvety texture. The pupil was oval vertically, measured 6 by 6.5 mm., and was fixed to direct and consensual light stimulation, accommodation, convergence, and noxious stimuli.

Gonioscopy under general anesthesia disclosed a wide angle, but a thick tissue resembling iris extended from the root of the iris to the lower part of the trabecula, obstructing a view of the scleral spur and ciliary sulcus. The optic disc showed marked glaucomatous excavation with nasal displacement of the vessels, and atrophy.

Venous pulsation was noted on the nerve-head.

Visual field with a 3/330-mm. white target revealed marked nasal constriction, especially inferiorly. The temporal field extended to 30 degrees, superiorly, and to 50 degrees, inferiorly.

Examination of the left eye was without significance except for gonioscopic findings. Vision was 20/30 (illiterate). The corneal diameter measured 10.5 by 10.5 mm.; iris and pupil were normal; tension was 25 mm. Hg (Schiøtz); fundus and visual fields were normal. Gonioscopically the entire angle anatomy was visualized, but many iris processes were observed to lie on a thin, gossamerlike, lightly pigmented structure in front of the angle markings; these findings were most pronounced nasally.

The elevated tension in the right eye failed to respond to pilocarpine and eserine, or doryl alone. However, following instillation of a drop of D.F.P., (0.1 percent) twice during one day, the tension was reduced to 8 mm. Hg for three days, rose to 20 mm. for three days, and then to 46 mm. Doryl (1 per cent, 3 times daily) was continued during this period. Three subsequent instillations of D.F.P. succeeded again in reducing tension to normal during the following 28 days of hospitalization.

The clinical diagnosis was congenital ectropion of the pigment border of the iris of the right eye, associated with embryonic mesodermal tissue in the angle and congenital glaucoma.

The normal pigment epithelium of the iris forms a double layer which just intrudes itself over the pupillary margin to form the pigment ruff. The flat, velvety appearance of the pigment in this case is due to simple overgrowth and eversion of the two layers of pigment epithelium, which remain in contact.

It is not known whether this is due to primary ectodermal hyperplasia or contraction of the anterior mesodermal tissue of iris stroma which pulls the pigmented edge over onto the surface of the iris. The condition is not hereditary and is thought to be due to a localized upset in the balance of growth rate of ectoderm and mesoderm. The suggestion has been made that this picture might be caused by conglomerate nevi.

The present case has been controlled for only a short time on strong miotics, and it is possible that goniotomy may have to be performed to free the filtration angle of the mesodermal tissue.

Granulomatous uveitis with hypersensitivity to streptococcus and staphylococcus

Dr. Fred Cox presented a man, aged 33 years, who was first seen at the Infirmary on August 2, 1947, with the complaint of redness, tearing, and pain in the right eye for six months. Treatment under the care of a physician during this time had been unsuccessful. He had a gonococcic prostatitis at the time of onset and was treated with penicillin and sulfonamides. The prostatic discharge stopped for a time but periodically reappeared although there were no gonococci found after the first course of treatment.

On admission, vision was: R.E., 20/100. The upper lid was edematous; there was moderate mixed bulbar injection. The cornea was clear with numerous large mutton-fat keratic precipitates scattered over the entire posterior corneal surface and a 2+ aqueous ray with numerous cells.

The iris was moderately dilated by mydriatics, showing many visible posterior synechias and many Koeppe nodules from the 10- to the 2-o'clock positions. The vitreous was clear, but the fundus was hazy, showing a normal disc and macula with no gross lesions in the periphery.

Vision was: L.E., 20/20. The eye was entirely normal and showed no evidence of uveitis.

General physical examination was negative except for chronic prostatitis. Blood Wassermann and Kahn tests were negative.

Sedimentation rate was slightly increased to 25 mm. per hour. X-ray studies of the chest, hands, feet, and teeth were normal. Brucellergin and P.P.D. intracutaneous tests were negative. Complement-fixation test for gonococcus and agglutination test for brucellosis were negative. Repeated smears and cultures of prostatic secretion on both blood and chocolate agar failed to show any gram-negative intracellular Diplococci. However, repeated cultures showed growths on both media of Staphylococcus and Streptococcus. Hospitalization treatment consisted of atropine (1 percent) locally, hot wet dressings, 5 million units of penicillin intramuscularly, local instillation of penicillin—5,000 units per cc. every 2 hours, and a series of typhoid injections up to 180 million organisms per cc.

Four weeks later, vision in the right eye had improved to 20/70, and he showed a mild mixed bulbar injection with scattered mutton-fat keratic precipitates and many cells in the aqueous. One week later the uveitis appeared to be as active as when first seen. On skin test with 0.01 cc. of a vaccine made of the organisms grown from the prostatic secretion, he showed a 2.5 cm. area of induration after 24 hours. Intramuscular injections of the vaccine were then begun, starting with 0.02 cc. and increasing 0.02 cc. with each injection twice weekly. After 12 injections there was definite subjective and objective improvement. At present there are only a few finely pigmented keratic-precipitate deposits, negative aqueous ray, with a few cells and no congestion of the iris. Vision is 20/70. The only other treatment during this time has been continuation of hot wet dressings and scopolamine.

Study of causes of blindness in Illinois

Dr. J. Robert Fitzgerald said that when the state of Illinois assumed from the individual counties of the state the responsibilities for the care of the indigent blind of the state, the administration of the aid to the blind was delegated to the Illinois Public Aid Commission and a medical advisory committee was named to advise on medical methods of procedure and standards of visual eligibility for blind-assistance applicants.

Recommendations of this committee were:

1. This definition of economic blindness: "In terms of ophthalmic measurement, central visual acuity of 20/200 or less in the better eye with correcting glasses is considered economic blindness. A peripheral field loss in which the visual field deficiency is reduced to 30 percent or less may be considered equally disabling, as may certain ocular conditions which do not necessarily involve visual acuity or peripheral field loss but which constitute a severe visual handicap."

2. All examinations for blind-assistance applicants be conducted by ophthalmologists certified by the American Board of Ophthalmology except in rural areas where such examiners were not available.

3. The adoption of an appropriate and complete ophthalmic medical record.

4. All blind-pension recipients who applied for state blind assistance be reexamined to determine visual eligibility with the exception of those in Cook County where all recipients had been reëxamined in the years 1941 to 1943 by competent certified ophthalmologists.

5. The appointment of a supervising ophthalmologist whose duties would be (1) To determine the visual eligibility for blind assistance of each applicant. (2) To classify the causes of blindness as developed by the Committee on Statistics of the Blind. (3) To transpose the essential medical and social information on blind-assistance recipients to a mechanical tabulating system. (4) To develop and activate a treatment program in the interests of restoration or preservation of vision. (5) To refer for vocational rehabilitation those hopelessly blind recipients who were deemed amenable to such training.

Accomplishments of this program were summarized by Dr. Fitzgerald.

1. The etiologic causes and the topographic sites of blindness have been carefully tabulated from the records of recent competent ophthalmic examinations. The facts obtained reiterate and reëmphasize the major unsolved problems of blindness and redirect our attention to the problems of prevention of blindness.

It is clear that primary glaucoma remains the greatest single source of blindness among all eye diseases in which restoration of visual loss is not possible. Until the problem of the etiologic cause and pathogenesis of glaucoma is clarified, the watchword should be early detection, adequate medical supervision with frequent and regular follow-up care.

Infectious diseases, traumatic injuries, and poisonings, representing approximately 31 percent of the causes of blindness, are definitely preventable.

Certainly the incidence of blindness attributable to general medical diseases could be reduced with proper and adequate care. The problem of prevention of blindness due to prenatal influences is vast and difficult but at least the surface has been scratched with the recent elucidation of the relationship of maternal rubella with congenital ocular defects.

In addition, it is possible that the majority of the 12 percent who were found to have remediable ocular conditions would not have remained blind if a good treatment program and competent ophthalmic advice had been available at the time of their original application for blind pension.

2. By the transference of the essential and pertinent information concerning blindness to a mechanical tabulating system, we will in the future be able to evaluate periodically our success or failure in those channels where we are now expending great efforts in the prevention of blindness.

3. As a result of standardizing visual eligibility for blind assistance throughout the state and placing the program under competent medical guidance, the visually ineligible recipients, constituting probably 10 to 15 percent of the total case load, have been weeded out and the administration of blind assistance has been removed from all political considerations.

4. A small percentage of recipients have as a result of surgical care been visually rehabilitated. The number of blind assistance recipients in Illinois who can be aided visually by corneal transplantation surgery is very small.

5. An indefinite but probably a considerable financial saving in the administration of blind assistance has and will continue to accrue to the state as a result of this program.

Cyclodialysis and iridectomy for glaucoma with cataract

Dr. Lyman A. Copps (Marshfield, Wisconsin) said that cataract often is found in glaucomatous eyes and many of these eyes require surgery for both conditions. Sometimes a cataract operation can be combined with a sclerectomy or iridectomy so that one operation satisfies them both. More often the glaucoma operation is done first and the lens extraction later, either because the tension in the eye cannot be reduced enough to render the combined operation safe or because the cataract is so incipient that its removal is not indicated when surgery must be done to control the glaucoma. It is not good surgery to do an extraction on an eye which has an elevated tension; the tension should be under control as a result of medical or surgical care at the time of the extraction and preferably for some time preceding it.

The many varieties of operations and their adaptations to the different types of glaucoma have been discussed widely, but less mention is given to the procedure of lens extraction in an eye on which a successful filtration operation has been done.

On the assumption that it is a bad prin-

ciple to disturb a well-functioning fistula operation, many surgeons prefer to extract the lens through an inferior incision; others make a corneal section below the fistula.

It is possible to cut boldly across a trephine opening and extract the lens through the usual limbus incision without ill effects. It would seem safer to dissect downward the original conjunctival flap and make the limbus section beneath it across the trephine opening or by enlarging the iridencleisis incision.

It has been said that the surgeon who is operating for glaucoma should devote his entire attention to the curing of the glaucoma, assuming that someone else is going to extract the cataract if one is present. It is better planning, however, to consider the problem in its entirety and to plan in advance the procedure or procedures necessary to provide vision in the eye.

The idea of combining cyclodialysis with iridectomy is not new. The operation was reported by Török in 1923; in 1927, Jervey reported a case and, in 1932, Wooten discussed a technique for the combined operation which varies somewhat from that which we have used. Wheeler recommended the operation for advanced and desperate cases and considered it too traumatizing for ordinary cases.

I do not recommend it for general use in glaucoma, even though I do not find it unduly traumatizing, but my experience leads me to believe that it may be suited to those cases of glaucoma where cataract extraction is not indicated at the time but is to follow later. I have not found it more traumatizing than other eye operations and the healing period has not been prolonged much, if any, beyond that of other operations for glaucoma.

The operation is done under local anesthesia, although sodium pentothal may be used. Butyn (2 percent) is first instilled into the conjunctival sac. A retrobulbar injection of 2 cc. of procaine hydrochloride with 3 min. of epinephrin hydrochloride is made and 2 min. of 5-percent cocaine hydrochloride are injected subconjunctivally at the 12-o'clock position near the limbus. Cocaine is used here because it controls the pain associated with the dialyzing process better than any other anesthetic.

A curved incision is made through the conjunctiva and Tenon's capsule 7 or 8 mm. above the limbus and parallel to it. The sclera is laid bare to the limbus widely enough to permit a satisfactory limbus incision—at least from the 10:30- to the 1:30-o'clock positions. It is extremely important that a minimum of aqueous be lost while doing the cyclodialysis and for this reason the incision through the sclera is made just wide enough to admit the spatula. This incision is made below the insertion of the superior rectus 5 or 6 mm. above the limbus at the 12-o'clock position. Because it is anticipated that extraction may follow, the 12-o'clock site is arbitrarily chosen; whereas, in simple cyclodialysis, the best site is that where the gonioscopic examination reveals the fewest adhesions.

The incision is made with a keratome or cataract knife obliquely downward through the sclera by short scratch cuts.

If the surgeon wishes to control the eyeball with O'Brien's scleral fixation suture, it must be placed before the scleral incision is made. If not, the sclera is grasped at the 6-o'clock position with a narrow-toothed scleral fixation forceps and depressed sharply.

A narrow-bladed angulated spatula is introduced into the suprachoroidal space and, hugging the sclera closely, it is brought downward into the chamber. Then by gentle pushing movements from above downward, the ciliary body is separated from the scleral spur. It is important to hold the spatula close to the sclera to prevent opening a channel through which aqueous can escape.

After withdrawing the spatula, the conjunctiva is lifted and a sharp keratome introduced into the chamber through the

limbus. If the keratome incision cannot be made wide enough without endangering the lens, it can be enlarged with scissors.

The iris is grasped widely and drawn out of the eyeball with good traction. The scissors hug the sclera closely and cut off the iris with three or four snips, the first and last cutting the sphincter. If iris remains caught in the ends of the incision, it is replaced with the spatula. If hemorrhage into the chamber has occurred during the cyclodialysis, it may be washed out with the chamber irrigator. Air can now be injected into the chamber as recently advocated by Barkan. The conjunctival incision is closed with fine silk sutures and atropine is instilled.

Thus far, this operation has been done by me only in advanced cases of glaucoma where it seemed imperative to control the tension in one operation, where a minimum of surgery was desirable, where satisfactory control of tension was not accomplished by miotics, and where some form of cataract was present.

Diathermy cauterization of ciliary body for glaucoma

Dr. Samuel J. Meyer presented a paper on this subject.

Cyclodiathermy puncture for glaucoma is safely indicated in cases where other surgical methods have failed, or where other surgical methods cannot be attempted. As a substitute operation, properly performed, it is of definite value.

Indications are: (1) Flat anterior chamber, especially after trephination or iridectomy; (2) aphakia, secondary glaucoma; (3) secondary glaucoma due to iris prolapse; (4) primary glaucoma where the chamber angle is obliterated, and where other operations are of questionable merit; and (5) hemorrhagic glaucoma.

The operative field is securely closed with a silk suture through the incised conjunctiva to prevent any secondary infection. There is practically no danger of any sympathetic infection occurring. Since 1881 (De-Wecker), and especially since 1925, many choroidal cauterizations have been done and no sympathetic ophthalmia has resulted. There is more risk of this occurring following a trephination.

For the practical ophthalmologist, the following facts are of importance: (1) Cyclodiathermy puncture is simple and safe, and can be repeated several times in malignant cases. (2) It is the only workable procedure in cases of a very shallow anterior chamber, (3) Cataract surgery in cases complicated by glaucoma need no longer be feared. (4) It is a conservative procedure in hemorrhagic glaucoma, especially after occlusion of the central vein. The operation may be repeated several times and enucleation may be prevented. (5) We do not have to fear secondary glaucoma, resulting from discission, vitreous hernia, or contusion of the eyeball.

A total of 142 cases were operated upon by cyclodiathermy puncture, but the histories of only 126 could be obtained for study. A result was considered successful if the patient was comfortable and relieved from pain, even though the tension was only reduced below 35 mm. Hg in 33 percent of the cases and below 30 mm. Hg in 28 percent. Up to the present time, 7 enucleations were necessary out of the total number of cases operated, and it is possible that more enucleations may be necessary in the future. There was complete relief from pain in 94 cases, or 74 percent, which is a satisfactory result, considering that most of these eyes had been operated upon previously and unsuccessfully; some having had several operations. The high percentage of relief from pain in hemorrhagic glaucoma should be noted, since this is a type of case which is not usually amenable to any form of surgical interference due to the newly formed blood vessels in the iris. Any surgical interference with the iris in such cases usually results in massive hemorrhage.

Discussion. Dr. Peter C. Kronfeld said

that the society is indebted to Dr. Meyer for a number of reasons. Several years ago when, to many ophthalmologists, the cyclodiathermy operation still appeared to be a dangerous and multilating procedure, he tried it on private and Infirmary patients and obtained gratifying results which he reported to this society. His results have continued to be very gratifying. He has stressed the true principle of the operation, the creation of multiple small foci of coagulation in the innermost layers of the sclera, indirectly affecting the outer layers of the ciliary body. The name "cyclodiathermy puncture" is, therefore, more to the point than the term "cyclodiathermy."

Dr. Meyer has devised a needle-shaped electrode with which the punctures, as well as the coagulations, can be performed safely and easily. It is somewhat thinner than the original Vogt needle and is very carefully insulated; only the needle itself carries the coagulating current and the places of entrance into the sclera are hardly visible.

This operation is a valuable addition to our surgical antiglaucomatous armamentarium. However, one tragic outcome has been seen at the Infirmary. A young lad with bilateral iridocyclitis and secondary glaucoma had been operated on at other institutions four times on the right and once on the left eye. Vision in the right eye was 15/200 and in the left eye, 20/40. The iridocyclitis appeared to be inactive in both eyes. On the right eye an iridectomy and several fistulizing operations had been performed without avail. On the left eye an iridectomy had been performed without avail. In both eyes, despite intensive medical therapy, the tension varied between 40 and 60 mm. Hg (Schiøtz).

On the better eye a cyclodiathermy puncture operation was performed with a needle that was not suitable for the purpose because of lack of proper insulation of its base. Each application of the needle, therefore, produced gross coagulation of the outer layers of the sclera, whereby considerable shrinkage of the fibrous coat and consecutive rise of pressure was caused. During and immediately after operation the condition of the eye did not seem in any way unusual. Forty-eight hours later, at the time of the first dressing, the patient complained of blurred vision, which was found to be reduced to just light perception. Examination of the eyegrounds revealed occlusion of the central retinal artery, believed to be caused by the rise in intraocular pressure caused by shrinkage of the sclera brought about by the unintentional surface coagulation. There was no return of vision in that eye.

Dr. Meyer stated that in 8 or 9 eyes in his series, enucleation became necessary. It would be interesting to know whether, in his opinion, the operation in any way contributed to the sad outcome. One would be inclined to think that cyclodiathermy puncture failed in that it did not prevent enucleation, but not by adding to the existing hypertension and irritation of the eye. In the last 50 cases on which this operation was performed at the Infirmary, no case was found in which cyclodiathermy puncture aggravated the situation to the extent that enucleation became necessary.

Cyclodiathermy punctures have been tried as a last resort in eyes with chronic simple glaucoma on which three operations had been performed, one fistulizing operation and two cyclodialyses, all of which had failed. In a series of such cases at the Infirmary, on which cyclodiathermy punctures were performed, in one third of the cases the ocular tension was reduced to below 30 mm. Hg. In another third of the cases, a beneficial effect could be noted in that the tension became definitely reduced. In the remaining one third of the cases, there was no demonstrable effect by operation. The price paid for normalization or reduction of tension in two thirds of the group was slight permanent diminution of corneal sensitivity. There is probably also some lens damage, although, in looking over the series at the Infirmary, no case was found where cyclo-

diathermy had greatly added to the existing cataract or produced lens opacity.

Referring to Dr. Copps's paper, Dr. Kronfeld said he had had some personal experience with that operation. Cyclodialysis and iridectomy seemed to suit a specific situation which he had had to face in China, where there was relative abundance of cases of corneal fistula with complete obliteration of the chamber angle. In most cases trachoma had led to considerable cicatrization and the results of external fistulizing operations were therefore poor.

By elimination, this operation of iridectomy combined with cyclodialysis was adopted with satisfactory results. He could give no definite data on results, principally because in those days there was not a proper follow-up of glaucoma in those patients.

In cases of corneal fistula it was found that the best method was to close the fistula by corneal transplant. Since the patients had become dependent upon the fistula for maintenance of normal ocular tension, an iridectomy was first performed combined with cyclodialysis; four weeks later the fistula was excised and closed by means of a transplant. Most patients stayed in the hospital or hostel for at least 6 to 8 weeks after the transplantation, and about half of the antiglaucomatous operations could be said to prove successful.

Dr. Kronfeld felt that both Dr. Meyer and Dr. Copps had presented very valuable antiglaucomatous procedures.

Dr. S. J. Meyer (closing) said that he had started to do this operation in 1940, shortly after reading Vogt's original article. The first case was a private patient who came to the office with a traumatic, hard, painful eye. Iridectomy was performed, but the eye became more painful and the question of enucleation was discussed. Following this operation there has been no pain, although there is a traumatic cataract for which nothing has been done. Shortly afterward, a number of cases were done at the Infirmary on eyes which were hard and painful following the original surgery, and in most of these the pain was relieved.

He had been impressed by the fact that as an end result the tension was not as low as had been expected in view of the results reported by others; in his series, tension remained high in about two thirds of the cases. All the enucleations were performed not because of surgical complications but because the operation had had no effect upon the pain. In one case, the patient was a diabetic who had bilateral hemorrhagic glaucoma; both eyes were operated on at one sitting and because infection developed in one eye it was enucleated.

In performing the operation, the effort is to go from the medial rectus to the lateral rectus, operate on the inferior half and avoid both medial and lateral rectus muscles, keeping away from the long ciliary nerve.

On the enucleated eyes, only one report is available. The eye was sectioned by the Army Institute of Pathology. Although the condition was far advanced, it showed only slight atrophy of the ciliary body.

If the operation was repeated, after failure of the first attempt which was carried out in the lower half, the punctures were made in the upper half.

DEVELOPMENT OF FIELD CHANGES IN GLAUCOMA

DR. ADOLPH POSNER and DR. ABRAHAM SCHLOSSMAN discussed this subject during the instruction period.

Gonioscopic studies of the canal of Schlemm

Dr. Peter C. Kronfeld of Chicago, said that the phenomenon which has been the starting point, as well as the nucleus of this work, is the appearance of blood in the canal of Schlemm in the normal eye. A preliminary report was presented before the Association for Research in Ophthalmology in 1942 (Am. J. Ophth., 25:1163, 1942).

During routine gonioscopic examinations of nonglaucomatous eyes a small percentage of cases show the phenomenon of sanguinous contents of the canal. If the gonioscopy is performed without a local anesthetic and without a contact lens of any kind, the region of the canal invariably proves colorless.

Blood is found regularly in the canal after aspiration of aqueous. If only a small amount of aqueous is withdrawn, the phenomenon can be seen to occur immediately and in close dependence upon the lowering of the intraocular pressure. Compression of the globe with the ophthalmodynamometer of Kukan is followed by a short phase of hypotony during which the canal can also be seen to fill with blood.

The phenomenon can also be produced by raising the venous pressure by means of a blood-pressure cuff applied to the neck. Mild degrees of compression (40 mm. of pressure) produce the phenomenon in 55 percent of control (nonglaucomatous, uninflamed) eyes. Dynamometry combined with neck compression of only 20 mm. produces the phenomenon in more than 90 percent of control eyes.

The gonioscopic observations essentially confirm the existing concepts concerning the canal and its connections with the vascular system and support the theory of a steady outflow of intraocular fluid through the trabecula-canal of Schlemm apparatus.

Bernard Kronenberg,
Secretary.

KATHERINE FERGUSON CHALKLEY, *Manuscript Editor*
Lake Geneva, Wisconsin

Directors: LAWRENCE T. POST, President; WILLIAM L. BENEDICT, Vice-President; WILLIAM A. MANN, Secretary and Treasurer; WILLIAM H. CRISP, FREDERICK C. CORDES, DERRICK VAIL.

Address original papers, other scientific communications including correspondence, also books for review to *Dr. Derrick Vail, 700 North Michigan Avenue, Chicago 11, Illinois;* Society Proceedings to *Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin.* Manuscripts should be *original copies,* typed in *double space,* with wide margins.

Exchange copies of medical journals should be sent to *Dr. F. Herbert Haessler, 324 East Wisconsin Avenue, Milwaukee 2, Wisconsin.*

Subscriptions, application for single copies, notices of changes of address, and communications with reference to advertising should be addressed to the *Manager of Subscriptions and Advertising, 664 North Michigan Avenue, Chicago 11, Illinois.* Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the *Manuscript Editor, Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin.* Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Ahnaip Street, Menasha, Wisconsin. if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

THE FIFTY-THIRD SESSION OF THE ACADEMY

Opening at the Palmer House in Chicago on October 10th, the American Academy of Ophthalmology and Otolaryngology held, as usual, a bigger and better meeting. The total registration was 4,364, including ladies and guests.

The ophthalmic instruction courses numbered 37 continuous and 101 individual ones. Twelve Home Study discussion periods were well attended and appreciated. At these periods, individuals enrolled in the Home Study group had the opportunity of meeting with their instructors and talking things over. Four afternoons were devoted to scientific papers and motion pictures in the Section on Ophthalmology meetings.

Out of 25 scientific exhibits, 15 were on subjects pertaining to ophthalmology. Dr. Kronfeld, Dr. Riser, and Dr. Parker received the first award for their fine and instructive exhibit on the physical changes of the eyeball in glaucoma. Col. Victor A. Byrnes (MC) of the School of Aviation Medicine, Randolph Field, Texas, received

the second award for his exhibit on training aids for ophthalmologic instruction. Dr. Payne, Dr. Burchell, and Dr. Krug were awarded the third place for their exhibit of specimens illustrating diseases of the eye. The excellence of all the ophthalmic exhibits was such that the judges must have had a difficult time of decision.

Each scientific session began with a clinicopathologic case report. This innovation was so well received that it is certain to be retained in subsequent programs. Those presenting case reports were Parker Heath, A. Edward Maumenee, M. Noel Stow, and John S. McGavic, who did their jobs efficiently and well. In each case, after discussing the clinical findings and diagnosis, the pathologic histology was illustrated with slides and correlated with the clinical signs displayed.

The supercolossal hit of the show was the symposium on primary glaucoma held on Monday afternoon, October 11th. Its purpose was "to discuss and evaluate the present trends of thought on the subject of primary glaucoma. A committee, with Dr. Derrick Vail as chairman, has been carefully chosen to undertake this task. An attempt has been made to integrate the various phases of the subject. The thoughts expressed in each paper have been agreed upon by the committee as a whole and thus they represent the combined opinion of the committee rather than the beliefs of any one individual."

The terminology, pathologic physiology, and symptomatology were given by Jonas S. Friedenwald; the diagnosis by Peter C. Kronfeld; the medical treatment by Harold G. Scheie; the surgical treatment by John H. Dunnington; the complications of surgery by Paul A. Chandler; and the review, summary, and conclusions were presented by the chairman.

Then followed a lively hour of questions from the floor directed to the appropriate members of the committee who gave their answers, which either brought out new points or clarified those that had been mentioned during the symposium. The success of this venture can be gauged by the fact that there was standing room only in the enormous meeting hall, and four hours later when the symposium had ended there were but a few vacant chairs.

The scientific papers read at the subsequent sessions were all of high caliber. Among those of exceptional interest and value were the following:

The paper by Christensen and Swan on "Epinephrine Antagonists in the Treatment of Glaucoma" disclosed the importance of the intravenous use of these sympatholytic compounds, primarily dibenamine, in the rapid reduction of the intraocular pressure in patients with acute primary glaucoma and to some extent in those suffering from some form or other of secondary glaucoma.

Alan C. Woods lucidly discussed the ocular symptomatology and pathology of sarcoidosis. Arthur C. Curtis, dermatologist of the University of Michigan, related his experience in the treatment of this common disease with calciferol and dihydrotachysterol. There seems little doubt that both of these agents are effective in controlling sarcoidosis.

The paper on "Reading Disabilities and the Ophthalmologist," by Ralph O. Rychener was timely and helpful. The author and his discussors pointed out that expensive and elaborate bits of apparatus are unnecessary in either the diagnosis or the treatment of reading disabilities in patients.

The paper by William C. Owens and Ella M. U. Owens on "Retrolental Fibroplasia in Premature Infants" had been long expected and anticipated. The authors related their important findings in the onset, course, and development of a retrolental membrane in the eyes of a number of premature infants under observation since birth. They expressed their opinion that "unknown etiologic factors must be at work during the postnatal life of the infant" to produce the

condition. In the discussion, Reese expressed his conviction that the anlage of the disease exists before birth and that only the extreme difficulty of examining the ciliary area of premature infants prevents its discovery immediately after birth.

Interspersed with the scientific program were motion pictures of ophthalmic interest. They were all of high quality and instructive. Three of these dealt with enucleation implants of various sorts employing various techniques. Time must elapse now in order to evaluate the different implants and the success or failure of the different techniques. At the moment it begins to look as if there were going to be as many different sorts of implants as there are speculums, capsule forceps, or methods of inserting sutures in cataract surgery.

On the first morning of the meeting and during the joint session, Jonas S. Friedenwald gave the Jackson Memorial Lecture, sponsored by this JOURNAL. His subject was "A New Approach to Some Problems of Retinal Vascular Disease." He disclosed that the Hotchkiss stain, selective for the polysaccharides in tissue, affects the basement membrane in blood vessels. By this method, the fundus findings in hypertensive retinopathy and particularly in diabetic retinopathy are clarified and allow for more accurate interpretation. During his able and excellent discourse, the audience could sense the excitement and thrill of the chase, as bit by bit the author disclosed his investigations and his deductions. The paper will appear in an early number of this JOURNAL and should open up many more studies of ocular vascular disorders.

From the viewpoint of social activities, there was little left to be desired. Each evening was taken up with dinners and reunions. Among the latter was the dinner of the ophthalmologists who had served together in the Army in the European Theater of Operations. A growing list of alumni dinners attests to the popularity of these affairs. The banquet came in for its share of the social events. Dr. Ernest Irons of Chicago, the president-elect of the American Medical Association, was the guest speaker of the occasion. Fourteen honor keys were awarded, seven to ophthalmologists for their years of devotion and loyal service to the Academy.

Dr. John McKenzie Brown was chosen president elect. Dr. Fred Dixon, Dr. Donald J. Lyle, and Dr. W. E. Keith were elected first, second, and third vice-presidents, respectively. The next meeting will be held in Chicago at the Palmer House, October 9 to 14, 1949. Derrick Vail.

SUPPOSE IT WERE YOUR NAME

A recent issue of *Time* magazine says that 75 percent of the American people know no other language than their own, and 50 percent do not wish to know any other. In this respect at least any careful observer would note how strikingly ophthalmologists resemble people.

Consider this incident. It was a bleak afternoon. The last patient had gone out into the gloomy winter twilight. The Old Man was at his desk puzzling over some obscure case records. A timid knock announced the new secretary.

"Excuse me, sir, but how do you spell 'jerrum'?"

"Spell what?", still absorbed in the records.

"Jerrum, sir. It doesn't seem to be in the dictionary. The letter says, 'the field shows a beginning jerrum—'."

"Oh, you spell it with a 'B'."

Finally conscious that the girl was still waiting, he looked up and said, "Sorry. You spell it B-j-e-r-r-u-m. And look here, that word is pronounced 'Byerrum'."

The secretary moved off rather doubtfully. A few minutes later she said, "I have found it."

"Something you lost?"

"I mean 'Bjerrum'. I found it in the dic-

tionary. And it isn't pronounced 'Byerrum'."

"What do you mean it isn't pronounced 'Byerrum'."

"I mean it isn't pronounced at all."

This is true. One elaborate medical lexicon in its last edition spells 'Bjerrum", but scrupulously avoids taking any chance on the pronunciation. From which you may draw any conclusion that appeals to you.

The mispronunciation of the name of this distinguished Danish ophthalmologist has always been a sick spot in American linguistics. The combination of "B" and "J" in the same syllable is incompatible with the American way of life. When they happen together as in "abject" and "object" the word divides. Twenty years ago the struggle to pronounce "Bjerrum" usually ended in an explosion like a suppressed sneeze. Recently the pronunciation has taken a distinct turn for the worse. Ophthalmologists who would be the first to snort at hearing someone speak of "Frood" or "Go-eethe" slip out "jerrum" without a tremor. Just what started this bit of illiteracy is a profound secret. Psychiatrists might conclude that it was initiated by someone who had been stung by a "B" in infancy. It certainly cannot be called Anglicizing the word. If the unabridged dictionary can be trusted this is the only instance in the language where an initial capital "B" has gone A.W.O.L. though the little ones occasionally escape. If you want to look up the word, the silent "B" is the letter you use. It may be too late to remedy this blunder. So fast has it spread that among men who know glaucoma best it seems to be "jerrum" two to one. To be sure, a candidate for the last Board Examination was heard to say "Byerrum," but he may have been from Minnesota, By Yiminy.

This is not true of another badly mangled word in the same category. According to a neighbor who has a backyard acquaintance with the Schiǿtz family, that word is neither "Sheeotz," nor yet "Shirts." He says the home-town sound is "Shuts," as in "Shuts the door." This is definitely simpler than any of the fumbles, and might make good on its merits.

For the fraction who are curious about phonetics, the Danish Consulate calls "Byerrum" correct.

S. Judd Beach.

CORRESPONDENCE

Argentine Congress of Ophthalmology

Editor,
American Journal of Ophthalmology:

Through the invitation of Moacyr Alvaro, secretary for South America of the Pan-American Association of Ophthalmology, I had the privilege of touring some of the principal cities of South America, visiting San Juan, Puerto Rico; Rio de Janiero, São Paulo, and Campinas in Brazil; Montevideo, Uruguay; Buenos Aires, Rosario, and Cordoba in Argentina; Santiago, Chile; and Lima, Peru, in the months of July, August, and September, 1947.

I had been invited to lecture and hold conferences on surgical subjects in each of these cities. I spoke in English and, through immediate translation into Spanish and Portugese, was able to make excellent contact with the ophthalmologists who came to the four lectures given in each of the cities. We were able to have questions and pointed discussions. Many of the South American ophthalmologists understand English well, so that it may have been tedious for them to go along with the translation, but they were the personification of courtesy and put up with my ignorance of their language. Mrs. Kirby and two of our daughters accompanied me and were charmed with the graciousness and hospitality of the ophthalmologists, their wives, and families. Their personal reception was such that we can never hope to repay them for their many courtesies.

My particular reason for writing to you now in my capacity as a member of the

Committee on Inter-American Relations of the Pan-American Association is to draw attention of the readers of the JOURNAL to the group of Amigos or Friends in Ophthalmology in North and South America. Much can be done to cement the wonderful friendships which have been established with our Latin American confreres. When any of them come to our cities, we should go out of our way to afford them every facility to visit our diagnostic, therapeutic, and surgical clinics and colleges and to attend lectures, meetings, and so forth. They do not ask for social entertainment. In fact, they are all modest and retiring and will not in any instance impose upon our time or hospitality.

In return, however, I can assure you that when any of you visit the South American cities you will find a very welcome greeting in their fine institutions, colleges, hospitals, and clinics. I can urge upon you tours of South America for study, for diagnosis, for therapy, and for surgery. You know the excellent caliber of the men from having personally met them in Cleveland and in Havana. Not many of you went to Montevideo. Now with the steamships of the Moore-McCormack, Delta, and Grace Lines and the planes of Pan-American and Panagra, there is no reason why we should not enjoy the beauties of South America, benefit by study there, and know our Amigos better.

As a starter, I can urge you to attend the Argentine Congress of Ophthalmology meeting in Mar del Plata, a beautiful seaside town about 250 miles south of Buenos Aires, December 13 to 18, 1948. I would urge that you go down one coast and come back the other. The trip by motor or by air over the Andes is a most thrilling and memorable experience. I am sure that all who go will treasure memories of their trip.

(Signed) Daniel B. Kirby,
New York.

BOOK REVIEWS

OPHTHALMOLOGY IN THE WAR YEARS. Volume II (January, 1944, to June, 1946). Edited by Meyer Wiener, M.D. Chicago, The Yearbook Publishers, Inc., 1948. 977 pages, subject and author indexes. Price, not listed.

The appearance of this volume brings to a close the work projected in 1943 when it was realized that the war disrupted the usual availability of ophthalmic literature, interfered with the harmonious collection of volumes for collecting and binding, and especially created a hiatus in the supply of current ophthalmic information to hundreds of ophthalmologists whose minds were otherwise occupied. With rare exception, the ex-medical officer would never go back over the journals published during the war years except to look for an occasional article.

Here, in the two volumes that cover the years from January, 1940, to June, 1946, are to be found the salient points from most, if not all, of the articles of ophthalmic interest that appeared during that time.

Of added interest and of great importance, is the running comment and criticism of the members of the editorial staff so ably marshalled by Dr. Wiener. Thus, the volumes are more than a collection of abstracts. They form a current and noteworthy textbook of ophthalmology, of valuable use in the preparation of an article or the evaluation of a new drug or surgical technique.

The list of contributors reads like a who's who in American ophthalmology. Each has done his part exceedingly well. The editor, Dr. Wiener, has skillfully arranged the material so that duplication, inevitable in this type of project, is minimized.

Those who have had Volume I since its appearance will need no urging to acquire Volume II. Those who do not possess the two volumes are depriving themselves of a very useful and valuable tool in their work. High praise and gratitude from all English-speaking ophthalmologists are due to Dr.

Wiener for his important contribution, and to his collaborators for their difficult and time-consuming efforts. It is a job well done by editor, contributors, and the publisher.

Derrick Vail.

DISEASES OF THE EAR, NOSE, AND THROAT. By William Wallace Morrison, M.D. New York, Appleton-Century-Crofts, Inc., 1948. Clothbound, 772 pages, 359 schematic illustrations. Price, $8.50.

Because of the intimate functional and pathologic relationship of the eye to the ear, nose, and throat, an understanding of the diseases of the latter is of fundamental value to the ophthalmologist. This up-to-date text by Morrison clearly and authoritatively synthesizes the current knowledge in this field. The common problems of specialists in the head area are well presented, such as the mechanism of headache and its differential diagnosis. He believes that half of the migraine cases can be relieved by careful allergic control. The excellent discussion of allergy and antihistaminic agents evaluates benadryl and pyribenzamine but not the newer drugs in the series such as antistine, neoantergan, neohetramine, theophorin, histadyl, decaprin, diatrin, trimeton, hydryllin, and so forth.

The infections and tumors extending from the sinuses to the orbit are adequately reviewed. Although he accepts multiple sclerosis as the predominant cause of retrobulbar neuritis, Morrison still considers that a small percentage of cases are due to extension of infection from the posterior ethmoid cells and sphenoid. In cavernous sinus thrombosis, since the causative organism is nearly always a Staphylococcus, Morrison considers penicillin the drug of choice, and also advises the use of heparin to prevent extension of the thrombus. The important eye signs in tumor of the acoustic nerve and in abscesses of the frontal lobe, temporal lobe, and cerebellum are given in detail.

Each chapter has bibliographic references, many of them as recent as 1946. The book closes not only with a subject index, but with an original and valuable symptom index as well.

James E. Lebensohn.

PRINCIPLES GOVERNING EYE OPERATING ROOM PROCEDURES. By Emma I. Clevenger, R.N. St. Louis, C. V. Mosby Company, 1948. 215 pages, 32 illustrations, index, and Foreword by Conrad Berens, M.D. Price, not listed.

Miss Clevenger has had many years of experience in an exceptionally busy eye operating room at the New York Eye and Ear Infirmary. Many splendid nurses, trained under her able direction, have carried her teachings elsewhere to the benefit of surgeon and patient. Many skilled ophthalmic surgeons owe much of their fame and success to the principles learned during their residencies surrounded by her influence. In giving us this unique book, she has added to our tools.

Her book covers everything pertaining to the smooth and efficient working of an eye operating room. It contains lists and photographs of instruments, "set ups," diagrams of supply tables, descriptions of pieces of electrical apparatus and their uses, as well as directions for the proper sterilization and care of instruments, equipment, and supplies. Furthermore, it tells us where to go to get the various articles used in the eye operating room. It is a most useful book for eye nurses and surgeons.

Derrick Vail.

BULLETIN OF THE SOCIÉTÉ BELGE D'OPHTHALMOLOGIE. No. 87. Meeting of November 30, 1947.

Of the 20 papers and case histories on various subjects one of the most interesting

presentations is L. Alearts's study on the aqueous humor which he considers to be a fluid common to the whole body "a real intercellular fluid" and not a fluid characteristic of the eye only. He defends his opinion with detailed arguments on the embryology, anatomy, physiology, pathology, and experimental chemistry of the aqueous and he outlines the clinical importance of this approach.

M. Appelmans and J. Michels discuss the experimental technique in the exploration of the blood-aqueous barrier. They found that gum arabic brought into the general circulation four days before followed a curve, similar to that of the passage of the proteins in the serum and in the aqueous as well. The secondary aqueous contained a larger amount than the first and it changed with the variations in the protein content of the circulation.

A. M. Potvin and Mlle. J. Helin present the ocular complications of pernicious anemia, complications which they consider to be vascular and toxic and not specific and, therefore, often difficult to diagnose.

M. Humblet emphasizes the importance of perimetry as part of every neurologic examination and as a preliminary test in ventriculography, arteriography, and even lumbar-puncture. He describes the possible field defects in median and lateral lesions of the chiasm. M. Wibo and J. Wibo recommend fistulating sclerectomy, iridectomy, and cauterization of the tip of the ectasia in corneal ectasia and they describe a case of their own.

Van Canneyt reports on heredofamilial lattice-shaped corneal degeneration and discusses the anatomy, pathology, etiology, and classification of this rare disease. A. Heintz suggests plastic surgery in cases of elephantiasis of the lids and presents two case histories.

M. Appelmans, M. Roeleus, and J. Michels discuss iridocyclitis with rheumatic spondylarthritis which in their opinion has the following characteristics: retrocorneal pannus, pigmented posterior synechias, an aqueous rich in proteins, mononuclear cells, no organisms even during the inflammatory spells, and frequent recurrences.

R. Hermans proposes the use of vitamin K in angioid streaks of the retina. Spells of violent headache, sudden change in the appearance of the streaks, hemorrhages around the streaks, and a low prothrombin time in patients with this disease were considerably improved by vitamin K. He also points out that vascular accidents in the stomach, intestinal tracts, uterus, nose, skin, and thyroid occur in these patients.

I. François reports a patient in whom a corneal transplant was successful, in spite of the rich vascularization of the cornea which followed a lime burn. L. Weekers recommends diathermy of the tarsus in cases of ptosis with paralysis of the levator palpebras and describes his technique for this operation. Van Canneyt and Kluyskens differentiate two forms of hysterical ptosis; hypotonic ptosis which is usually bilateral and associated with a contracture of the frontal muscle and other paralytic symptoms and the spastic ptosis or pseudoptosis without contracture of the frontalis which is usually monocular and accompanied by clonic spasms and trembling.

In his paper on posttraumatic herpes zoster ophthalmicus, J. Zanen reviews 36 cases from the literature and presents a case of his own. He is somewhat skeptical about a relation between herpes zoster and trauma. He insists on the recognition of a time limit of 5 to 15 days as the incubation period of the zoster virus from the traumatized skin or mucous membrane.

A. Hoorens contributes a study on the pharmacologic reactions of the pupils. L. Weekers and R. Weekers, A. Heintz, and

F. Roussel give a statistical report on the anatomic and functional results after surgery for retinal detachment. A. Benoit describes an ocular injury caused by podophyllin powder resulting in a severe infiltration of the cornea, a yellow discoloration of the iris, and exudation into the vitreous. The outcome was favorable.

This volume also contains a paper on the X-ray treatment of bilateral retinoblastoma by F. Roussel, the description of two unusual cases of thrombosis of the cavernous sinus by De Jaeger and A. De Haene, and W. Baekeland's report of an osteoma of the nasal orbital wall.

Alice R. Deutsch.

TRANSACTIONS OF THE SOCIÉTÉ D'OPHTHALMOLOGIE DE PARIS. Meetings of June and October, 1947.

This volume of 115 pages brings a report of the meetings of the société d'ophthalmologie de Paris, held on June 21, 1947, and October 18, 1947. Twenty-three papers and case histories were presented.

E. Haas discusses the uveal complications of gonorrhea. G. Offret presents a case of uveitis and opticochiasmatic arachnoiditis. P. Bregeat takes the opportunity to outline the characteristics of corneal vaccinola after having described an observation of his own. Monbrun's and J. Lavats's study on the effect of streptomycin on miliary tuberculosis and tuberculous meningitis is of special interest because it emphasizes the importance of the ophthalmoscopic examination as a guide on the regression, extension, or stabilization of the main lesions. J. Sédan and S. Sédan-Bauby discuss the provoked diplopia which, they believe, is an improvement in evaluation of muscular deficiency in regressive paresis and in the exact classification of heterophorias and convergence anomalies.

Other papers of interest include the description of an orbital metastatic neoplasm which appeared several years before any clinical manifestation of the main tumor (Pivolean and G. Offret), a recurrent iridocyclitis following a blunt injury of the other eye (P. Designes and Nandin), the treatment of myopia gravis (J. Gallois), the history of an optic neuritis caused by food poisoning (E. Leseune), and a case history of tularemia, interesting because of the peculiarity of its localization, the lack of general symptoms of the disease, and the etiology—the scratches of a cat. Retinal hemorrhages in tuberculous persons, the mechanism of the allergic reactions, and the condition of the neurovegetative system were the topic of C. Boudon's paper.

Among the papers presented at the meeting of October 18th, special emphasis should be given to the work of Paufique, G. Offret, and Vouters on neurofibroma, because of their detailed study on the pathology of orbital tumors.

Baillart's lecture on endoscopy revives the observation of several visual phenomena and their explanation. Toulard made bacteriologic studies of corneas, 1 to 5 hours after death, none of the microörganisms found were pathogenic.

Various rare case histories are presented, among them a suprasellar cholesteatoma, keratoplasty with a living graft, monocular exophthalmus caused by a hemorrhage into the contralateral frontal sinus together with a retrobulbar hemorrhage, a pterygium which recurred in spite of conjunctival and corneal plastic surgery, and a patient with an adherent leukoma in whom repeated keratoplasty was successful.

M. Lenoir summarizes the present knowledge on contact glasses. G. Offret presents Vassiliev's paper on the probing of the lacrimal passages, a procedure which he favors

in noninflammatory stenosis. A. Gauthier and G. Bruys show several graphs in proof of their theory on the seasonal occurrence of retinal detachment in Algiers. They found the peak to be in April and June.

Alice R. Deutch.

LEHRBUCH DER AUGENHEILKUNDE. Edited by A. Amsler, A. Brückner, Franceschetti, H. Goldman, E. B. Streif. Basel, Switzerland, S. Karger, 1948. 858 pages, 342 illustrations including many in color, 4 tables, index. Price, 85 Swiss francs.

Anyone familiar with the German textbooks of ophthalmology published before the war, such as that of Axenfeld, will be struck by the similarity between this splendid volume and those published by Springer. I refer to the format and beautiful illustrations and diagrams. It may be a very long time before the textbooks of Germany appear once more. It is highly significant, therefore, that Karger conceived the idea of publishing a textbook of ophthalmology in German to be written by outstanding Swiss ophthalmologists. It is evident at once that he has succeeded in his project, for here is a modern and complete textbook that reflects great credit on its editors, collaborators, and the publisher.

The collaborators include, Babel, Bangerter, Bischler, Blum, R. Brückner, Bürki, Huber, Klein, Lüdin, Lutz, Süllmann, Weve, and Wolf-Heidegger.

The wish expressed by the editors in the Foreword that, "this textbook, the first of its kind to appear in Switzerland, will receive a warm reception," is certain to be fulfilled.

Derrick Vail.

ARQUIVOS DA CLINICA OFTALMOLOGICA DO HOSPITAL MILITAR PRINCIPAL. Lisbon, v. 1, 1944-45.

This report contains a biographical note on the founder of the clinic, several historical notes, nine reports of extensive original work, and an assortment of clinical and therapeutic notes. Four of the original papers are on trachoma; one records the first case of Crouzon's disease to be described in Portugal and another a case of Tay-Sachs's disease. There is an analysis of work of 10 years in the ophthalmological clinic of the Military Hospital S. Miguel, Azores. In a brief report the effect of vasodilators on the retinal arteries is demonstrated by a pair of fundus photographs.

F. H. Haessler.

ABSTRACT DEPARTMENT

EDITED BY DR. F. HERBERT HAESSLER

Abstracts are classified under the divisions listed below. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

1. Anatomy, embryology, and comparative ophthalmology
2. General pathology, bacteriology, immunology
3. Vegetative physiology, biochemistry, pharmacology, toxicology
4. Physiologic optics, refraction, color vision
5. Diagnosis and therapy
6. Ocular motility
7. Conjunctiva, cornea, sclera
8. Uvea, sympathetic disease, aqueous
9. Glaucoma and ocular tension
10. Crystalline lens
11. Retina and vitreous
12. Optic nerve and chiasm
13. Neuro-ophthalmology
14. Eyeball, orbit, sinuses
15. Eyelids, lacrimal apparatus
16. Tumors
17. Injuries
18. Systemic disease and parasites
19. Congenital deformities, heredity
20. Hygiene, sociology, education, and history

1

ANATOMY, EMBRYOLOGY, AND COMPARATIVE OPHTHALMOLOGY

Danis, P. C. The functional organization of the third-nerve nucleus in the cat. Am. J. Ophth. 31:1122-1131, Sept., 1948. (7 figures, references.)

Vos, T. A. Iris numerata. Ophthalmologica 115:354-358, June, 1948.

In the case reported normal iris crypts happened to be situated in such a way that they formed a dark figure 2 which was very striking against the background of the light grey iris. The author concedes priority for this observation to M. van Duyse who suggested the term "cipher iris" in 1903. Peter C. Kronfeld.

2

GENERAL PATHOLOGY, BACTERIOLOGY, IMMUNOLOGY

Bietti, G. Ultravirus in ocular pathology. Boll. d'ocul. 27:1-19, Jan., 1948.

Bietti presents an extensive review of the present knowledge of the ocular localization of various virus diseases. The difficult problem of the Rickettsias is discussed with particular reference to their relation to trachoma. It is suggested that this disease is caused by a Rickettsia.

K. W. Ascher.

Fridenberg, Percy. Mechanical factors in ocular pathology. Am. J. Ophth. 31: 1002-1003, Aug., 1948.

Missiroli, G., and Scano, A. Effect of the lacrimal fluid on the respiration of bacteria. Boll. d'ocul. 27:41-53, Jan., 1948.

Tears were collected from the lower fornix of numerous normal and pathologic eyes by means of a sterile pipette, then diluted with physiologic saline solution and stored in the refrigerator. Suspensions of the bacteria to be tested were prepared and the oxygen consumption was measured in the Warburg apparatus at a temperature of 38°C. The results are represented in three tables and graphs. It was found that tears inhibit the respiration of lysosensitive bacteria completely. The respiration of lysoinsensitive organisms is not modified. It was not possible to prove a bacteriostatic effect of the

lacrimal fluid on organisms during active multiplication or at rest.

K. W. Ascher.

Rapisarda, D. **Concerning tuberculous allergy and the eye.** Rassegna ital. d'ottal. 17:128-145, March-April, 1948.

Rapisarda stresses the fact that ocular tuberculosis is an affection dependent upon a general disease and that the phenomena of allergy and immunity are characteristic of the particular tissue involved. This explains the polymorphous appearances of the ocular involvement. He emphasizes the conception of the importance which the allergic state bears in the pathogenesis of ocular tuberculosis and its possible interference in nontuberculous and traumatic lesions. The practical methods adopted to study tuberculous allergy are discussed, among them the "patergico" method, which permits a quantitative evaluation. In the evaluation of the allergicometric results one must remember that the presence of a morbid ocular bacillary focus probably alters the harmony between the allergic orientation of the ocular membranes and the skin.

The analytic examination of the results obtained by the clinical and experimental studies of the author support the conviction that there exists no parallelism between cutaneous and visceral allergy. Many aspects of ocular tuberculosis can thus be explained in the light of a dual concept of allergy. Eugene M. Blake.

3

VEGETATIVE PHYSIOLOGY, BIOCHEMISTRY, PHARMACOLOGY, TOXICOLOGY

Aguilar Bartolomé, J. M. **The effect of some vaso-dilators on general blood pressure, the retinal vascular pressure, and the intraocular pressure.** Arch. Soc. oftal. hispano-am. 8:468-477, May, 1948.

This is a graphic report of an investigation on men between 20 and 30 years of age. The vasodilators used were nicotinic acid, and a mixture of calcium chloride with magnesium thiosulphate. The ocular tension, the retinal vascular pressure, and the general blood pressure were taken twice before the injection of the vasodilator, immediately afterwards, 15, 30, 40, 50 and 60 minutes later, and after 2 and 24 hours. The oral administration of nicotinic acid was without effect on the intraocular pressure or the retinal pressure; parenteral administration was equally without a significant effect. The intramuscular or intravenous administration are similar in effect, differing only in the intensity and latent period; the intraocular tension falls 2 to 4 mm. Hg, the diastolic retinal pressure falls 2 to 3 mm., the systolic retinal and the venous pressures remain unaffected. The effect lasts one hour. Mydriasis was observed in two of the ten patients studied. The magnesium combination is effective only in intravenous administration and the effect is proportional to the quantity injected. After some fluctuation the tension remains lower than normal for a period of 2 to 24 hours; the time depends on the dose. There is no effect on the retinal circulation. A combination of nicotinic acid and the magnesium mixture eliminates the initial fluctuations in the ocular tension and produces an immediate reduction of tension that lasts 24 hours. The other pressures show no significant change. (7 graphs.) Ray K. Daily.

Bárány, E. A. **The influence of alteration of the vasomotor system of the eye in relation to the local arterial blood pressure and the intraocular pressure. An investigation of the homeostatic reflexes.** Rev. oto-neuro-oftal. 22:73-78, July-Aug., 1947 and 22:104-110, Sept.-Dec., 1947.

Previous similar studies yielded no real evidence that a mechanism described in

the title exists in the eye. The author exposed one common carotid artery and made pressure on it. He measured the ocular tension in both eyes, before, during and after pressure and when the test animal was warmed and chilled. Similarly, tests were performed after the administration of adrenalin, cocaine, ephedrine, ergotamine, prostigmine, and atropine, and after cervical sympathectomy. Occlusion of the carotid artery caused a slight decrease in the intraocular tension (4 mm. Hg). Drugs and cervical sympathectomy did not have an appreciable influence on the relation between the eye pressure and the lowered blood-pressure. The author concludes that there is still no proof of the existence of a homeostatic vasomotor reflex mechanism to protect the intraocular pressure from changes occasioned by alterations in the blood-pressure.

Edward Saskin.

Bárány, E. and Davson, H. **A note on the physiology of the aqueous humour.** Brit. J. Ophth. 32:313-314, May, 1948.

This very short article is an extension of the opposing views of Bárány and Davson as to whether salts in the aqueous are secreted by the lining membranes or whether they enter the aqueous by simple diffusion from the blood stream. Since blood pressure and ocular pressure have no effect on the salt content and salts are not secreted exclusively by the membranes of the aqueous chamber neither theory is satisfactory. The problem of the secretion of salts into the eye, therefore, remains in a state of flux. A mere mathematical analysis of data already to hand is not sufficient for a decision.

D'Ermo, Franco. **Action of murexine, a new choline derivative, on the iris muscle of the horse and the cow.** Boll. d'ocul. 26: 763-766, Dec., 1947.

In the dye-producing organ of the snail Murex trunculus there is at least one substance which has a definite effect on stripes of iris tissue of the horse and of cattle. Isolated stripes of sphincter and of dilatator tissue were exposed to acetone extracts of 0.02 to 2 mgm. of the posterior median zone of fresh hypobranchial organs of the snail. The contraction of the iris stripes was proportionate to the strength of the solution, and atropine in concentration 1 to 500,000 did not inhibit or counteract the effect. Blood serum and brain tissue extracts did not have any influence on the action, neither did the addition of diazoparanitroaniline salts of formaline in concentrations between 1 to 1,000 and 1 to 10,000. Boiling for ten minutes in one-tenth-normal sodium hydroxide solution, however, inactivated the extracts. The effect of more distant parts was much less pronounced than the region mentioned above. The action of the organ extract was three to six times as strong as that of acetylcholine. All these qualities would suggest that the substance that acts so strongly on the horse iris is murexine (Erspamer and Dordoni, Ricierca Scientifica, 16, 1946). Similar results were obtained on the iris sphincter of the ass and on that of the calf, in the latter however to a lesser degree. The same extracts acted about one thousand times more strongly on the sphincter strips than on the dilatator of the horse iris. (2 graphs.)

K. W. Ascher.

Dordoni, Franco. **Dionin and histamine; the mechanism of its local action.** Boll. d'ocul. 27:20-40, Jan., 1948.

On 34 adult cats the development of ethylmorphine hydrochloride chemosis was studied and compared with the action of the same drug after previous local or systemic application of 2 (N-phenyl N-benzyl aminomethyl) imidazoline methansulfate, named Antistin Ciba, and of 2 N-dimethylamino 2 propyl-thiodiphenylamine-Cl, named 3277 R.P. Rhône Poulene. Local application of Antistin did not interfere with the dionin chemosis; subcutaneous administration, however, reduced the chemosis or even abolished it without reducing the hyperemia. Similar effects were obtained by subcutaneous 3277 R.P. administration. High atropine doses did not produce any similar effect. Histamine solutions do not fail to increase the filling of the conjunctival vessels when antihistamine substances have previously been administered parenterally. The chemosis seems to be due to a histamine-like tissue mediator whereas the hyperemia after dionin most probably results from a direct action of this drug. Repeated instillations of dionin over periods of from 4 to 10 days and repeated instillations of 0.2 percent histamine solutions did not interfere with the action of the other drug respectively. The habituation to dionin does not involve the production of hyperemia but the chemosis is less marked. The habituation to dionin is ascribed to a failure to release the tissue mediator. (9 tables, references.) K. W. Ascher.

Fanta, H. **The effect of pilocarpine on normal eyes.** Ophthalmologica 115:338-353, June, 1948.

After two instillations, two minutes apart, of equeous pilocarpine solutions of varying strength, the ocular tension, the width of the pupil and the refractive state of normal human eyes were followed for periods up to 24 hours. During the first 30 minutes the tension was determined tonometrically every two minutes. On the whole the effect of pilocarpine on the normal eye was slight and inconstant. About one-third of all subjects tested showed no measurable lowering of the ocular tension. In the remaining two-thirds the tonometer revealed a drop up to 6 mm. Hg (Schiøtz). The concentration of the pilocarpine solution influenced the duration but not the magnitude of the reduction of tension. The miotic effect was more pronounced and much more constant. No parallelism between miosis and ocular tension could be recognized. The miosis nearly always outlasted the lowering of the ocular tension. The cyclotonia following pilocarpine was very variable and difficult to measure. The concentrations of the drug tested were ¼, ½, 1, 2 and 100 (crystals) percent.
Peter C. Kronfeld.

Kapuściński, W. **Observations on the pulse and retinal arterial pressure.** Brit. J. Ophth. 32: 273-300, May, 1948.

In this very long article, the author records many observations on the pulsations of the central retinal artery and reaches new conclusions about the mechanics of the pulsation and circulation of the blood. In almost no textbooks of physiology is the mechanism of the pulse described with any degree of detail or truth. It is simply stated that the palpable pulsations are due to dilatation of the artery during the force of systole and contraction during diastole. This theory is completely untenable. The pulsation of the retinal artery is simultaneous with the pulsation at the wrist and is assumed to have the same origin; despite this rhythmic pulsation which is seen in 80 percent of people, the artery does not change in width or caliber during the pulsation but simply undergoes a temporary change in position. This is also true at the wrist or the temple. The arterial tube would increase in size with an increase in its internal pressure and volume

and if it did increase in caliber during systole, this increase would result in a lowered intravascular pressure instead of an increase. The author concludes that the blood stream in the vessels is uniform. It circulates without any oscillations due to pressure, so that there is no difference between diastolic and systolic pressure. During systole, the blood circulates faster imparting to the column of fluid a kinetic energy which results in the pulsations seen and felt.

Morris Kaplan.

Leoz de la Fuente, G., and Bartolozzi Sánchez, R. **Modifications in the retinal arterial pressure through compression of the common carotid.** Arch. Soc. oftal. hispano-am. 8:457-467, May, 1948.

This is a detailed report, with tabulated data, on the effect of a two-minute compression of the common carotid artery on the retinal vascular circulation. Since this reaction depends on the compensatory function of the cerebral circulation in the circle of Willis, it is suggested that exploration of the retinal response to carotid compression may be used clinically to determine the functional state of the cerebral compensatory circulation, preliminary to ligation of the common carotid. This investigation comprises ophthalmodynamometric measurements in forty patients, in the recumbent position. One investigator took the retinal pressures and the other exerted the compression. The data show that during the compression the pressure in the retinal vessels is nil, or very low. Two minutes later it rises and the diastolic pressure may reach its original level, but the systolic remains not less than 23 percent below its normal level. There are two patterns of behavior of the diastolic pressure: a juvenile in which the reduction of pressure does not exceed twenty percent, and a senile in which it is over twenty percent. There were patients over fifty years of age in the juvenile group and young people in the senile group. The vascular age of a patient may not coincide with his chronological age. A fall in the diastolic pressure of not over twenty percent indicates a satisfactory collateral cerebral circulation; a fall between 20 and 50 percent suggests good cerebral compensation that is subject to unpredictable variations. A fall above 50 percent is definitely a sign of poor collateral cerebral compensation. A marked difference in the systolic pressure of the two eyes is pathognomonic of poor circulation in the region of the common and internal carotid arteries particularly if the lower systolic pressure remains unaffected by compression of the common carotid of the same side, but falls after compression of the common carotid of the opposite side. The response in the retinal vascular pressure to carotid compression is attributed to an autonomous cerebral mechanism rather than to a direct effect of the compression on the carotid sinus; this assumption is supported by the quantitative dissociation of the diastolic and systolic pressures after homolateral carotid compression, and by the fact that continued compression of the carotid leads to a rise in the diastolic pressure of the opposite eye in 50 percent of subjects and in the systolic pressure in only 30 percent. A direct effect from the carotid sinus would be expected to exert the same influence on the two pressures.

Ray K. Daily.

Matteucci, Pellegrino. **On the autonomous regulation of the uveal vessels.** Ann. di ottal. e clin. ocul. 73:126-127, Feb., 1947.

If sympathetic gangliar synapses exist in the vessels of the choroid, the passage of central vasomotor stimuli through them would be inhibited by the action of nicotine. Matteucci found that vasodilatation could be ophthalmoscopically ob-

served alike in nicotinized and normal eyes when the carotid sinus was electrically stimulated; hence he concluded that the perivascular nerve fibers of the choroid in the albino rabbit (his experimental animal) have no gangliar synapses and therefore the choroidal vessels do not possess, as far as the present evidence goes, an autonomous regulatory system of their own. Harry K. Messenger.

Miller, B. **The effect of Priscol upon the retinal arteries.** Ophthalmologica 115: 11-21, Jan., 1948.

Priscol is a vasodilator related to histamine which European authors have used in the treatment of circulatory disturbances of the retina, as well as in inflammatory and traumatic diseases of the anterior segment of the eye. Miller has made actual measurements of the caliber of the retinal vessels under the influence of Priscol. With a heliometer eye piece in an ophthalmoscope of the Gullstrand type, Miller measures the width of all retinal arteries and veins near the disc. By dividing the sum of the widths of the arteries by that of the veins he arrives at a quotient that expresses the relative caliber of the arteries. In patients with signs of retinal angiospasm, Priscol in doses of 0.01 grams given intravenously 6 to 10 times over a period of 2 weeks produces a marked dilation of the retinal arteries and a moderate drop in blood pressure. The dilation of the retinal arteries may be associated with subjective and objective improvement of vascular retinal disease.

Peter C. Kronfeld.

Moreu, Angel. **Physiopathology of the irido-ciliary innervation.** Arch. Soc. oftal. hispano-am. 8:578-589, June, 1948.

The author reviews the recent literature on accommodation, and reports the data on his own investigations on the physiology of the ciliary muscle. A subconjunctival injection of adrenalin in atropinized eyes increases the mydriasis somewhat, and slightly impairs visual acuity for distance; this impairment can not be corrected with lenses, but at night vision improves with a minus 1.50 sphere. It is pointed out that variations in visual acuity for distance are more easily demonstrated in reduced light and at night. Intense eserinization produces a marked approximation of the punctum proximum, without any effect on visual acuity for distance. After an injection of gynergen the punctum proximum recedes somewhat. The double innervation of the ciliary muscle differs radically from that of any other pair of muscles with reciprocal innervation, in that paralysis of one nerve exerts no effect on its antagonist.

Another approach to the physiology of the ciliary muscle was made through gonioscopic examination of iridectomized eyes. After extracapsular extraction eserinization of the eyes produced visible relaxation of the zonule and an increased folding of the lens capsule with forward propulsion of the vitreous. The instillation of atropine was followed by a recession of the ciliary processes, with no significant effect on the lens capsule, although the zonular fibers appeared more tense. Subconjunctival injection of adrenalin produced a reaction similar to that of atropine, and the injection of gynergen was gonioscopically without effect.

The state of our present knowledge on the mechanism of accommodation is summarized as follows: accommodation for near is produced by a change in the chronaxia of the third nerve, or through the action of metabolites that cause contraction of the circular fibers of the ciliary muscle which in turn act on the zonule of Zinn. The vitreous participates in this process. There is also probably an

accommodation for distance, through the radial portion of the ciliary muscle. This negative accommodation is less in intensity, range, and significance than accommodation for near, and does not exceed two diopters. It appears certain that the action of the two parts of the ciliary muscle have different functions; it has not been possible to demonstrate the existence of a tonus between the two antagonistic portions of the ciliary muscle. The existence of two muscular antagonists, without a tonus is of great physiologic interest, and calls for revision of Sherrington's work. Ray K. Daily.

Rademaker, G. G. J., and Ter Braak, J. W. G. **On the central mechanism of some optical reactions.** Brain 71:48-76, 1948.

Four reactions were studied experimentally: 1. the blinking reflex elicited by a threatening movement and by the sudden unexpected approach of an object near the eye, 2. the conjugate ocular movements excited by optic stimulation, 3. the optic placing reactions of the forelegs, and 4. opticokinetic nystagmus. Reactions 1 to 3 were studied with dogs, 4 with pigeons, rabbits, cats, dogs, and rhesus monkeys. The first is a cerebral reaction, and still occurs when only the small lateral and caudal part of the striate area is spared surgically. In 2 the removal of the whole caudal part of the striate area abolishes the movements, whereas they still occur after extirpation of the lateral and caudal and also of the rostral part of the visual cortex. Reactions 3 are cerebral in origin, remaining when the whole caudal part of the striate area has been removed and only a small rostral part of the visual cortex spared. Reactions of the fourth group have not been proved to be cerebral. A long discussion of opticokinetic nystagmus follows. (7 figures, references.) Bennett W. Muir.

PHYSIOLOGIC OPTICS, REFRACTION, COLOR VISION

Bennett, A. G. **The optics of contact lenses.** Brit. J. Ophth. 32:257-272, May, 1948.

By means of numerous detailed Gaussian formulas, the optics of contact lenses are explained and many of the sources of error in the prescription and manufacture of these lenses are revealed. Since it is extremely difficult optically to make an afocal lens it is better to incorporate added power in the contact lens than to let the fluid lens correct the refractive error. This is now being done in most of the new lenses. In anisometropia, contact lenses do not abolish the difference in the size of the images but they avoid the unequal vertical prismatic effects arising from ordinary spectacles when the eyes rotate to view objects above or below the horizontal plane. In unilateral aphakia, contact lenses have a similar advantage. The previously emmetropic eye that has become aphakic has a retinal image about 25 percent larger than its fellow when the correction is worn 12 mm. from the cornea. Contact lenses reduce this disparity to about 9 percent and in many cases this renders binocular fusion possible. Morris Kaplan.

Brozek, J., Simonson, E., and Franklin, J. C. **A note on methodological evaluation of selected visual tests.** Am. J. Ophth. 31:979-984, Aug., 1948.

Candian, L. **The factors in the improvement of vision in myopic eyes following Fukala's operation.** Ann. di ottal. e clin. ocul. 73:193-220, April, 1947.

The improvement in visual acuity after Fukala's operation is often greater than can be explained on photo-optical grounds alone and must be attributed to the improved circulation, nutrition, and func-

tion of the choroid and retina. The lowering of the intraocular pressure, which is commonly observed after the operation, is thought to account for the improved condition of the tunics of the eyeball. With lowered intraocular pressure there is less tension on the tunics and the tendency to stretch is diminished; the choroidal vessels are better filled, and the retinal elements are closer together and are better nourished. One may believe that the eyeball itself undergoes some shortening after the operation by contraction of the elastic fibers in the sclera when the tension is lowered.

Candian analyzes the pertinent literature and reports a series of his own (14 eyes). In one eye he observed that a "Fuchs's central black spot" actually regressed after extraction of the lens and all but disappeared.

The factors are listed in the following order:

1. The lowered intraocular pressure brings about an improved condition of the ocular tunics. 2. The retinal images are larger. 3. The simplified optical system minimizes the dispersion of light (only one refracting surface as against five in the corrected myopic eye). 4. In consequence of the improved distance vision the functional capacity of the retina is increased. (Bibliography.)

Corrado, Mario. **Influence of the spatial extent of the light stimulus on the pupillomotor reflexogenic power of the retina. (Pupillomotor reflexometric curve.)** Ann. di ottal. e clin. ocul. 73:171-182, March, 1947.

The same exponential curve for the pupillary reflex is found whether the retina is excited with light stimuli of increasing intensity, or stimuli of constant intensity but applied over an increasingly great area of the retina. In obtaining the curves care was taken to confine the stimuli to the foveal and perifoveal region. Similar curves have been found for the visual responses to light stimuli. Whether the visual and pupillary responses are mediated by one and the same or by two types of fibers, the point of departure for each response seems to be the retinal cone. Harry K. Messenger.

Corrado, Mario. **The behavior of certain entoptic phenomena occurring in an eye subjected to compression. Their significance in relation to the general problem of the biophysical mechanism of vision.** Ann. di ottal. e clin. ocul. 73:257-289, May, 1947.

Corrado reviews the literature on entoptic phenomena produced by pressure on the eye. Experimenting on himself, he observed, in addition to the usual well-known phenomena, that the macula, which appears entoptically at first as a dark elliptical disc, gradually, as the pressure is increased, becomes very brilliant, with finally a small very dark more or less polygonal spot in its center. The dark phase of the disc is attributed to perimacular circulatory changes, and the brilliant phase is thought to be due to electrochemical stimulation of the rods and cones. From his studies he concludes that vision is a combination of two factors, electric and chemical.

Light perception, color perception, and visual acuity are diminished as the pressure on the eye is increased. (9 figures, bibliography.) Harry K. Messenger.

Del Zoppo, Italo. **Vision with the eyelids closed (a study of the absorption of luminous energy by the lids).** Ann. di ottal. e clin. ocul. 73:247-255, April, 1947.

In making this study Del Zoppo used Maggiore's photometer, controlled with a photo-electric cell, and Corrado's pupillometer. Both instruments are described. Determinations were made by stimulating one eye and by observing the con-

sensual pupillomoter reflex in the other eye by means of the pupillometer. The threshold for colored lights except red was found to be approximately the same as for white. Red, despite its greater power to penetrate the tissues, has a considerably higher threshold. It is absorbed by the lids more than the other colors, probably because the blood in the lids serves as an absorption screen. An average stimulus of 0.6 lux, that is, an intensity 30 to 50 times greater than with the eyes open, is required to elicit the pupillomotor reflex, and the threshold is somewhat higher in elderly persons than in the young. Absorption by the lids is very great for low intensities and diminishes as the illumination is increased. (Bibliography.)

Harry K. Messenger.

Farnsworth, D. **Need for informative labeling of sun glasses.** Tr. Am. Acad. Ophth. pp. 366-370, March-April, 1948.

The purpose of this article is to dissipate the superstitions about the value of sun glasses by a summary of the simple facts. If an individual in a particular circumstance feels no eyestrain, does not squint, and is not irritated emotionally, there appears to be no reason why he should wear sun glasses. One of the best methods of protection against glare is afforded by shielding of the eyes from light from above, below, and from the sides. Most glare seems to be peripheral glare. Lobstermen's caps, which have greatly elongated visors, are efficient. We must largely rely on a simple glass which mitigates glare by reduction of intensity of light rather than by eliminating peripheral light. It should be nearly neutral in color, transmit 10 to 20 percent of the light and transmit very little energy below 400 microns or above 700 microns. Broad, well-fitted lenses should exclude peripheral light.

Sun glasses should be worn in exceedingly strong light, heat, and high altitudes, and in ordinary intensities by people whose eyes are hypersensitive. They should be worn by individuals newly subjected to unaccustomed intensities. They should not be worn when the illumination level is low and should never be worn for night driving.

Sun glasses can only be intelligently selected if the manufacturer will clearly label his product as to its essential characteristics. Chas. A. Bahn.

Guggenbuehl, A. **The dependence of stereoscopic vision upon the state of light adaptation. Ophthalmologica** 115:193-219, April, 1948.

The acuity of binocular depth perception of light-adapted eyes has been determined by many investigators with many different methods. Little attention has been paid to the influence of dark adaptation upon the acuity of stereoscopic vision. A previous paper from the same clinic (Gaus, Ophthalmologica 112:267, 1946) concerned itself with the acuity of binocular depth perception by means of eccentric retinal areas. In the paper under review this work is being extended to include eyes in the state of dark adaptation. The method is again that of Monje (Zeitschr. f. Sinnesphys. 69:73 and 69:261) the principle of which is the observation by the examinee of three black parallel threads while they are slowly being rotated from the initial horizontal (parallel to the interpupillary line) to the vertical position. From the beginning of the rotation the center thread is placed a little closer or farther than the other two threads. This disparity is not recognized by the examinee while the threads are in horizontal position. The angle of rotation at which the disparity becomes perceptible is a measure of the acuity of binocular depth perception. Under the specific conditions of the test (on examinees conditioned by

previous similar examinations) the author obtained acuities of binocular depth perception of 10 to 15 seconds of arc for the light-adapted and of 47 to 61 seconds for the dark-adapted eye. Both values, but especially the latter, were lowered by practice. In the periphery of the retina the decline of the acuity of binocular depth perception closely paralleled the decline of monocular visual acuity. As far as the binocular perception of depth is concerned, cones proved 1.5 times as sensitive as rods of the same retinal area.

Peter C. Kronfeld.

Hecht, S., Shlaer, S., Smith, E. L., Haig, C., and Peskin J. C. **The visual functions of the completely colorblind.** J. General Physiol. 31:459-472, July 20, 1948.

The visual functions of a completely colorblind individual are compared with those of the normal. The sensibility distribution in the spectrum has a maximum at 520 mμ at all brightnesses and thus corresponds to rod vision alone. This is confirmed by studies of dark adaptation which show final thresholds like those usually found for rod vision. Dark adaptation, measured both centrally and peripherally in the retina, is a single continuous function, and regardless of the brightness of the preceding light adaptation, is of the rapid type only, such as that found for the normal after low light adaptation. Visual acuity is also a single continuous function like rod vision. Both critical fusion frequency and intensity discrimination show two sections, one at low and the other at high intensities with a sharp transition from one to the other. Intensity discrimination is as good as in the normal eye, and covers much the same range. The maximal critical fusion frequency is only about 20 cycles per second as compared to 55 cycles for the normal. The two sections shown by the colorblind eye for intensity discrimination and fusion frequency possess the spectral sensitivity of rod vision since the relative positions on the intensity scale are not influenced by using different parts of the spectrum. (9 figures, references.)

Bennett W. Muir.

Hodel-Boos, M. **The perception of movement under conditions of dark- and light-adaptation.** Ophthalmologica 115: 25-46, Jan., 1948.

This study was undertaken because of the occurrence (in Switzerland) of apparently typical accidents during the long dim-out periods of the last war. Not recognizing the state of motion of a streetcar people got off too soon and fell. The author determined the threshold for the sensation of movement of various patterns moving horizontally across the field of the examinee. These determinations were made under conditions of central as well as eccentric vision, on light-adapted and dark-adapted normal human eyes. The latter recognized the state of motion of the pattern at an objective speed three to four times as great as that necessary to create the sensation of motion in a light-adapted eye. In addition to this difference in thresholds, the recognition of motion by the dark-adapted eyes was less certain than that of the light-adapted eye. Thus, the author believes to have found a physiologic explanation for the accidents mentioned before. The psychologic aspects of the perception of movement are discussed. Peter C. Kronfeld.

Imus, H. A. **Visual testing technics.** Tr. Am. Acad. Ophth. pp. 370-385, March-April, 1948.

The technical merits of the principal industrial screening gadgets are discussed. These include the Ortho-Rater, Sight-Screener, Keystone and Massachusetts Tests. The reliability and Pearsonian coefficients as well as other technical details are presented. A few practical ideas which present the subject from the

potential user's standpoint are mentioned. Generally speaking, the Orthorater and Sight Screener are best adapted for the rapid screening of large groups in which the initial cost is a negligible factor. The Keystone equipment is in the intermediate group and the Massachusetts and similar tests are best adapted for screening smaller groups, especially primary grade children in which time is a lesser factor and initial cost more important.

Chas. A. Bahn.

Lenoir, M. (with collaboration of M. G. Rose). **Tolerance to plastic contact glasses.** Arch. d'Opht. 8:49-53, 1948.

The authors note the lack of data on the toleration of the normal eye for contact glasses. Some ophthalmologists consider a glass clinically useful if it can be tolerated for two or three hours whereas others consider only ten to twelve hours of continuous wear as the criterion of usefulness. The symptoms of intolerance includes pain, discomfort and visual disturbances. The authors designate the factors leading to intolerance as mechanical or optical. Under mechanical factors they include the dimensions of the glass, its weight, and its adaptation to the eye. They note that the eye ought to be able to move in all directions without conjunctival compression or shift of axis by the glass. The weight of the glass can be reduced by making the scleral portion thinner than the corneal. The scleral fit should be such that there are neither tight nor loose areas. There should be no contact with the cornea or limbus. The optical conditions should be such as to correct the ametropia accurately. Prismatic effects should be eliminated. The authors have modified the ordinary plastic lens by cutting small grooves in the inner surface of the scleral portion in order to facilitate circulation of tears. They consider that artificial fluids should be only exceptionally required.

The authors conclude that certain persons can tolerate plastic lenses indefinitely but that others, in spite of the utmost care in fitting, are relately intolerant because of factors not yet understood.

Phillips Thygeson.

Moron-Salas, José. **The exploration of aniseiconia.** Arch. Soc. oftal. hispano-am. 8:363-367, April, 1948.

Moron-Salas describes a simple quantitative test for vertical aniseiconia. It consists in placing before one eye a figure that consists of a central horizontal line with a dot 10 cm. from it on each side and before the other eye a Maddox double prism with the bases of the united prisms in the pupil. The resulting binocular figure consists of a continuous line and doubled dots on each side. In the presence of aniseiconia the separation between the dots is unequal, and by measuring the difference in their separation in mm. the amount of aniseiconia can be calculated, from a computed table. (1 table.)

DIAGNOSIS AND THERAPY

Arruga, H. **Treatment with products of tissue disintegration according to the method of Filatoff.** Arch. Soc. oftal hispano-am. 8:404-406, April, 1948.

This method of therapy is described by Arruga principally on the basis of information gathered by him from the abstracts in the American Journal of Ophthalmology. Ray K. Daily.

Callahan, Alston. **Bipronged forceps; an instrument for plastic surgery.** Am. J. Ophth. 31:1165-1166, Sept., 1948. (2 figures.)

Debré, R., Monbrun, A., Thieffry, S., Brissaud, H.-E., and Lavat, J. **Ophthalmoscopic examination in miliary tuberculosis in the infant.** Arch. d'opht. 8:129-149, 1948.

This report was based on a study of 135 patients treated with streptomycin at the Hospital des Enfants-Malades, Paris. The success of streptomycin in miliary tuberculosis is increased by early diagnosis and early use of the drug. Ophthalmoscopic examination is of value in early diagnosis. In 120 cases of tuberculous meningitis, tubercles of the choroid were recognized on first examination. Tubercles were found in 23 of 35 patients with miliary tuberculosis on initial examination, and of nine cases in which the X-ray findings were doubtful, diagnostic fundus changes were present in five. Ophthalmoscopic examination was also of value in prognosis and as a guide to treatment in cases of relapse. Ophthalmoscopic examination is difficult in the infant but that with appropriate mydriasis and with patience a satisfactory examination can be made.

Phillips Thygeson.

Dekking, H. M. **Opacity meter for cornea and lens.** Ophthalmologica 115:219-226, April, 1948.

Rønne devised the "colloidometer" for measuring the opacity of the aqueous by comparing it with the opacity of the cornea of the same eye. The variability of the latter in the same and in different eyes is the main objection to Rønne's method. In 1936 Dekking devised an opacity meter which uses an invariable "physical" opacity standard. The instrument has been improved and is now described in detail. In principle it consists of an optical system that forms an image of the eye or its parts in the focal plane of an ocular. Adjacent to this image and in the same plane is a photometer field with variable and measureable brightness. The light source serving the photometer is a constant fraction of the light source illuminating the eye. Theoretically only light reflected at right angles to the line of incidence should be used for opacity measurements. This requirement has only been partly met. Light reflected specularly from the surfaces of cornea and lens is prevented from entering the system in appreciable amounts. A number of precautions have to be taken in making the measurements. No practical applications or results are reported. The instrument is apparently not being manufactured. Peter C. Kronfeld.

Friedenwald, Jonas S. **Some problems in the calibration of tonometers.** Am. J. Ophth. 31:935-944, Aug., 1948. (11 figures.)

Friedenwald, J. S. **Recent advances in tonometer construction.** Tr. Am. Acad. Ophth. pp. 543-547, May-June, 1948.

The Sklar instrument employs a small mirror in the tonometer scale to reduce errors of parallax in reading. The hammer is epicycloid in form rather than concave as in the conventional Schiøtz design. Errors due to lateral play of the plunger and to friction between the hammer and plunger are thus reduced. In the Harrington tonometer accuracy in reading is greatly increased by the use of a 360-degree dial disc. A transparent plastic foot facilitates accurate centering on the cornea. In the electronic tonometer an electrical system of making manifest the position of the plunger replaces the usual mechanical type. An induction coil is placed within the brass cylinder attached to the foot plate and the tonometer plunger forms the core. Although free from frictional difficulties, new electrical problems such as sensitivity to input voltage fluctuations exist. The sensitivity of this instrument is two to four times that of conventional mechanical tonometers. Chas. A. Bahn.

Froschauer, W. E., and Schrimpf, C. E. **Pentothal sodium in the aged with respect to eye surgery.** Geriatrics 3:231-236, July-August, 1948.

There are no contraindications to the use of sodium pentothal in the aged. The authors use sodium pentothal for basal anaesthesia and add regional and instillation anaesthesia. I. E. Gaynon.

Fuentes Noya, M. **A new blepharostat.** Arch. Soc. oftal. hispano-am. 8:611-614. June, 1948.

This blepharostat was designed for the removal of foreign bodies under slitlamp control. It is small, suitable for both eyes, and its chief merit is that, unlike most blepharostats, it remains in position with the patient seated in front of the slitlamp, and does not interfere with the manipulations necessary to remove a foreign body focused under the corneal microscope. (2 figures.) Ray K. Daily.

Gallois, J. **Action of minimal elective vasodilatation in chorioretinitis and in senile retinas.** Rev. oto-neuro-oftal. 22: 78-80, July-Aug., 1947.

A case of senile retinal degeneration with poor vision and contracted fields is presented in which vision and fields improved after treatment with nicotinic acid. Similarly, a patient with disseminated chorioretinitis showed improvement when treated with benzyl imidazoline. The author recommends low doses of vasodilators for their nutritional effect on the choroid and retina. Edward Saskin.

Gát, L. **Lid evertor for mucous membrane grafting.** Ophthalmologica. 115:47-48, Jan., 1948.

To facilitate the dissection of mucous membrane flaps from the oral cavity the author has devised three "evertors" which work on the principle of solid cylindrical supports for the tissue that is worked upon. Peter C. Kronfeld.

Haik, G. M., Breffeilh, L. A., and Barber, A. **Beta irradiation as a possible therapeutic agent in glaucoma. An experimental study with the report of a clinical case.** Am. J. Ophth. 31:945-952, Aug., 1948. (8 figures.)

Horner, Warren D. **A dependable tying forceps for fine sutures.** Am. J. Ophth. 31: 1001, Aug., 1948.

Hruby, K. **Further simplifications of the technique of slitlamp microscopy of the posterior segment.** Ophthalmologica 115:290-296, May, 1948.

To facilitate slitlamp microscopy of the posterior segment by means of a strong concave lens placed a short distance in

front of the eye, Hruby has devised a lens holder and a fixation light both of which are attached to the support against which the examinee rests his head. The lens holder permits the accurate centering that is essential for the recognition of the finer details in the vitreous. The fixation light which the patient watches with his other eye facilitates maintenance of the required position and thereby shortens the examination. Peter C. Kronfeld.

Kelly, T. S-B. **A low power infra-red microscope.** Brit. J. Ophth. 32:396-397, July, 1948.

An infrared microscope which projects its image on a flourescent screen is described. It is actually part of a binocular slitlamp, of which the source of light is an infrared image converter tube that draws its energy from a 12-volt battery. The instrument will probably be most useful in the penetration of corneal opacities, pupillary membranes, and aftercataract. Morris Kaplan.

Knapp, A. A. **Night-blindness and vitamin D.** Rev. oto-neuro-oftal. 22:82, July-Aug., 1947.

Night-blindness may be based on an ocular or systemic disorder and is frequently considered a manifestation of vitamin A deficiency. The author finds that patients with ordinary night-blindness including the nyctalopia of myopia, are aided by vitamin D and calcium, and advises a therapeutic combination of vitamins A and D, and calcium.

Edward Saskin.

Matas, B. C. **Slitlamp microscopy of the fundus.** Ophthalmologica 115:179-185, March, 1948.

Optical conditions suitable for slitlamp microscopy of the fundus can be created by means of a contact lens or of a strong minus lens placed in front of the eye. The former method was devised and elaborated by Koeppe in 1918. The latter was first described by Lemoine and Valois in 1923 and recently readvocated by Hruby. In the paper under review Matas compares the two methods with regard to the smallest pupil that permits binocular observation and the size of the fundoscopic field. By simple calculations he arrives at the result that the contact lens requires a lesser degree of mydriasis of the patient's eye than the strong minus lens. The contact lens also yields a larger fundoscopic field. Obvious advantages of the strong minus lens are the accessibility of more peripheral fundus areas and the wider applicability, especially in eyes recently operated upon.

Peter C. Kronfeld.

Missiroli, G., and Corelli, F. **Antiexudative therapy by plasma transfusions in sympathetic ophthalmia and in other eye diseases.** Boll. d'ocul. 26:737-748, Dec., 1947.

Plasma transfusions proved to be of benefit in different internal morbid entities characterized by inflammatory exudative changes, therefore the authors expected good results in eye diseases with an inflammatory exudate. They used transfusions of 20 to 200 cc. of human plasma in 8 patients with sympathetic ophthalmia, 16 with traumatic iridocyclitis, 9 with tuberculous uveitis and 4 with recurrent vitreous hemorrhages. The intervals between injections were two to five days and two to fifteen transfusions were administered. If after the third or fourth transfusion no effect became manifest, the treatment was discontinued; in some eyes good results were noted after the second transfusion. In the eight cases of sympathetic ophthalmia the results were unexpectedly good; 25 to 50 days sufficed to effect a clinical cure. The results in posttraumatic iridocyclitis were favorable, but in tuberculous uveitis and in recurrent vitreous hemorrhages unsatisfactory.

K. W. Ascher.

Rosso, Silvio. **Histomorphologic modifications induced in the ciliary ganglion and in the retro-ocular nerve trunks by the retrobulbar injection of alcohol.** Ann. di ottal. e clin. ocul. 73:97-106, Feb., 1947.

Dogs were given a retrobulbar injection of 80 percent ethyl alcohol, and the ciliary ganglia were removed 5 to 20 days later for examination. Both degenerative and regenerative phenomena were found, especially in the smaller paragangliar nerve trunks and in the more peripheral cells of the ganglion itself. It is inferred that the ganglion, despite its small size, offers a certain resistance to the penetration of the alcohol. The smaller nerve trunks are more vulnerable but tend to regenerate, whereas the alterations in the ganglion cells appear to be irreversible. This may explain the relatively rapid reestablishment of corneal sensitivity after injection, and the more permanent absence of pain. Harry K. Messenger.

Stein, Lester. **Flexible cable slit control for biomicroscope.** Am. J. Ophth. 31: 1166-1167, Sept., 1948. (1 figure.)

Toulant, M. **Tissue therapy in ophthalmology.** Arch d'opht. 8:33-48, 1948.

Toulant reviews the work of V. P. Filatov, director of the Institute of Experimental Ophthalmology of Odessa, and of his students, on tissue therapy in ophthalmology. The review is based principally on Filatov's latest book (1945), entitled "Corneal grafts and the therapeutic utilization of preserved tissues." The review presents the history of the method which began in 1933 with the observation of the clearing of a corneal graft after the use of nonpenetrating limbal grafts of preserved cadaver tissue. Filatov concluded that the graft carried stimulating substances in the nature of hormones which developed in the tissues as a result of unfavorable conditions in vitro. As practiced by Filatov, tissue therapy includes injections of cod liver oil as well as subconjunctival or subcutaneous implantations of cornea, skin cartilage, retina, choroid, placenta, brain, spleen, liver, muscle, and nerve tissue. The tissue fragments are sometimes used intact, sometimes minced, and sometimes as aqueous extracts.

Clinical results are claimed in such diverse conditions as sclerokeratitis, rosacea keratitis, herpetic keratitis, tuberculous uveitis, keratoconus, myopic chorioretinitis, retinitis pigmentosa, and optic atrophy. Certain inconclusive laboratory studies are cited. Toulant concludes that only extensive and controlled clinical studies can demonstrate the value of the method and that up to now only inconclusive studies have been made outside the U.S.S.R. Phillips Thygeson.

Traquair, H. M. **Symposium on headache as a symptom. IV. The eyes and headache.** Edinburgh M. J. 55:180-182, March, 1948.

The author presents the ophthalmologic viewpoint in a symposium on headache as a symptom. There appears to be no correlation between the ocular refraction, nor the demands made upon the ciliary body and headache. Treatment consists in the use of suitable spectacles to relieve any difficulty in achieving the maintenance of efficient binocular vision which is a frequent cause of headache. In all cases it is necessary to examine and treat the patient and not only the eyes.

Orwyn H. Ellis.

Weidmann, W. **A simple accurate self-recording perimeter.** Ophthalmologica 115:332-337, June, 1948.

The perimeter consists, in principle, of a hollow hemisphere made of transparent plastic with a thin, translucent coat of dull white paint on its outer surface. The perimeter target is a small electric bulb which is moved along the outer surface by a mechanism invisible to the exam-

inee. By means of diaphragms and filters interposed between the electric bulb and the outer surface of the perimeter sphere a light spot of variable size and color is projected onto the inner surface of the perimeter sphere and thus serves as perimetric target. The instrument is manufactured by the firm of M. J. Purtschert in Luzern (Switzerland).

Peter C. Kronfeld.

6

OCULAR MOTILITY

Adler, F. H. **Some confusing factors in the diagnosis of paralysis of the vertically acting muscles.** Tr. Am. Acad. Ophth. pp. 447-457, May-June, 1948.

In the first group discussed, the motor anomalies observed cannot directly be explained by a single lesion. For example, the subjective and objective symptoms which suggest a paralysis of the superior or inferior rectus muscle of one eye, combined respectively with superior or inferior oblique paralysis of the other eye, is not explainable by a single, nuclear or internuclear lesion. Motor limitation is quantitatively and qualitatively dependent upon which eye is chosen for fixation, a fact that is not sufficiently emphasized nor illustrated in ophthalmic literature. Many factors individually and collectively determine the master or fixing eye. Under some circumstances an eye with a paralyzed muscle becomes the fixing eye, for example, when in right superior rectus paralysis the antagonist of the weaker muscle in the fixing eye (right inferior oblique) will move with relatively less effort than normal, and its yoke muscle in the other eye (left inferior rectus) will therefore also tend to overact. This results in an apparent weakness of the antagonist (left superior oblique) in the other eye. Obviously, such a diplopia cannot be explained by a single nuclear or internuclear lesion because the process is largely supranuclear.

In the second group discussed, a single lesion such as a pontine hemorrhage may cause unusual vertical motor abnormalities. This results from the small size and close proximity of the nuclei from which the third and fourth cranial nerves arise.

Chas. A. Bahn.

Braun-Vallon, S., and Hartmann, E. **Retinal correspondence in strabismus.** Ann. d'ocul. 181:321-337, June, 1948.

A brief résumé of the several theories and types of strabismus is followed by a description of the more frequent tests and examinations which involve retinal correspondence. Among these are the red glass test, the Lancaster, the synoptophore, and the recurrent image test. If the abnormality with the recurrent image test is similar on several different weekly tests the lack of retinal correspondence is probably not recent, and therefore the prognosis is less favorable. This is especially true if synoptophore results correspond. If the abnormal retinal correspondence as shown by the Bielschowsky recurrent image test is variable on several occasions the prognosis is better, especially if the abnormality as tested with the synoptophore and red glass tests is constant. The prognosis is best if the recurrent image test on several occasions shows normal retinal correspondence, the other tests, abnormal.

Occlusion, orthoptic exercises and surgical procedures are discussed at some length. Before operation is decided upon, a series of ten to twelve half-hour sessions of orthoptic training are given in the course of three or four weeks. If retinal correspondence is normal at the end of this time the prognosis for surgical procedures is most favorable. When only partial improvement follows, the prognosis for structural and functional cure become less. The progress of 19 patients with strabismus is analyzed and several illustrative cases are presented.

Chas. A. Bahn.

Eyles, Marianne. **Barriers and aids to fusion.** Am. J. Ophth. 31:1147-1151, Sept., 1948. (Discussion by G. S. Campion.)

Gardilčić, A **A new ptosis operation: tucking of the levator muscle.** Ophthalmologica 115:269-282, May, 1948.

Through a skin and orbicularis incision the levator muscle is exposed just above or posterior to the beginning of its aponeurosis. At a level dependent upon the degree of the ptosis three sutures are inserted into the levator. These sutures are now enclosed in the upper tarsus and tied, as a result of which the levator is folded or tucked to a degree that depends upon the places of insertion and final anchorage of the sutures. The operation is easy to perform, easy to repeat in case of under-correction and is relatively atraumatic. Peter C. Kronfeld.

Hornbogen, D. P. **An operation for shortening a rectus muscle.** Am. J. Ophth. 31:1164-1165, Sept., 1948. (4 figures.)

Sedan, J., and Sedan-Bauby, S. **Pathologic physiology of induced diplopias.** Arch. d'opht. 8:233-327, 1948.

The authors describe a prism test designed for the detection and investigation of latent oculomotor deficiencies. The test is performed by placing before the suspected eye a powerful prism of from 30 to 45 degrees. The two eyes are allowed to remain open during the period of study which may be from 30 to 60 minutes. The diplopia must be maintained during this time. In the normal subject the diplopia disappears instantly when the prism is removed, but in the subject having a previous ophthalmoplegia the diplopia persists for an appreciable time (15 minutes to 12 hours). In one case the induced diplopia lasted 60 hours. The diplopias so created are then studied by the usual methods and the offending muscle or muscles identified.

The authors discuss in detail two possible explanations for the phenomenon. The first hypothesis suggests that an atony of the previously paretic muscle is produced by excess of contraction; the second suggests that the atony results from a passive stretching of the muscles. The authors believe the test will render considerable service in neuro-ophthalmologic studies. Phillips Thygeson.

Stein, A., and Bangerter, A. **Orthoptic treatment.** Arch. d'opht. 8:156-168, 1948.

Stein and Bangerter describe in detail the methods employed in the school of orthoptics at the ophthalmological clinic of Saint-Gall in the treatment of amblyopia, strabismus, and heterophoria. Training instruments and apparatus developed at the school are described and illustrated by photographs. The school is divided into two classes, one for monocular education and the other for binocular education. The authors stress that in the treatment of the amblyopia it is not the duration of the occlusion that matters but the intensity of the use of the eye during the occlusion. The children attend the school for one hour three times weekly. The first half hour of classwork is devoted to monocular or binocular work with the various training instruments, and the second half hour is devoted to games designed to develop binocular vision. In addition, home exercises are prescribed. A chart is appended which gives a schematic plan for the management of strabismus from its development to the age of six years when treatment should normally be concluded.

Phillips Thygeson.

Vos, T. A. **Simplified resection of the lateral or medial rectus muscle.** Ophthalmologica 115:22-24, Jan., 1948.

The author's method is essentially a tucking with resection of the tendon-muscle fold. Blaskovics' triple-armed silk suture is used to unite the muscle stumps and to close the capsular and conjunc-

tival wound. According to the author, the advantages of this operation are that it is a quick procedure, requiring little or no assistance, the apposition between muscle stump and original insertion is very accurate, the sutures are deeply and securely placed and the scar is hardly noticeable. Two clear diagrams illustrate the author's technique. Results are not given. Peter C. Kronfeld.

Yasuna, Elton. **A technique for muscle resection without the use of the Prince forceps.** Am. J. Ophth. 31:972-974, Aug., 1948. (4 figures.)

7

CONJUNCTIVA, CORNEA, SCLERA

Ayberk, Nuri F. **Superficial punctate keratitis.** Göz Kliniği 6:43-48, May-June, 1948.

Six cases seen in Turkey, where the disease is generally unrecognized, are reported. There was no relation to other disease; the lesions were limited to one eye and consisted of superficial grayish nodules on the cornea, hyperemia without secretion of the conjunctiva, pain, and photophobia. Bacteriologic examinations were negative. F. H. Haessler.

Barazzoni, Antonio. **An initial corneoconjunctival epithelioma with incipient differentiation towards Poleff's papillomatous type.** Ann. di ottal e clin. ocul. 73: 290-301, May, 1947.

A case of corneoconjunctival tumor in a 52-year-old woman is presented. There had been antecedent trauma. In accordance with Poleff's scheme the tumor was classified, on the basis of its histologic peculiarities, as an initial epithelioma with incipient differentiation towards the papillomatous type. The clinical and histologic characteristics and the classification of neoplasms of the corneoconjunctival epithelium are discussed. (1 illustration, 6 photomicrographs, bibliography.) Harry K. Messenger.

Chavarria, F. A. **Disciform keratitis in the new-born.** Arch. Soc. oftal. hispano-am. 8:607-610, June, 1948.

A case of typical disciform keratitis, in an infant 13 days old, caused by injury with the forceps during delivery, is reported. After the instillation of pilocarpine for four months the dense central opacity in the middle parenchymal layers of the right cornea cleared up sufficiently to permit a view of the fundus. The unusual feature is the recovery, which is attributed to the favorable effect of the pilocarpine on the ocular nutrition and absorption of the exudate.

Ray K. Daily.

Crespi Jaume, G. **Symmetrical dystrophy of the corneas.** Arch. Soc. oftal. hispano-am. 8:603-606, June, 1948.

This is a report of a very unusual case. A woman, 40 years old, had bilateral, diffuse, symmetrical opacities limited to the lower half of the corneas and denser in the center. The upper halves of the corneas were completely transparent. The demarcation between the involved and clear zones was very sharp, and at the level of the edge of the upper lid. The lower half of the cornea had a granular appearance, resembling somewhat Fuchs's dystrophy, or glaucomatous edema. The structure of the iris could be distinguished indistinctly through the epithelial opacity which extended to the limbus in the entire semicircumference. In front of the pupillary area the opacities were larger, denser, more sharply circumscribed, and separated from one another by clear zones. The patient suffered intermittent acute attacks, with pericorneal injection, lacrimation, and superficial vascularization at the limbus which lasted about two

weeks. Visual acuity was 2/3. She had no other disturbances and the family and personal history were negative. Therapy with vitamins, ointments, and occlusion was without effect. (1 figure.)

Ray K. Daily.

Edmunds, Mead, and Beck, Regena. **Rhinosporidiosis of the conjunctiva, case report.** Virginia M. Mo. 75:278-280, June, 1948.

Rhinosporidiosis is a fungus infection primarily of the nasal mucous membranes. It produces a polypoid growth resembling granulation tissue which bleeds readily. The source is unknown. It occurs in young males. It appears on the conjunctiva as a painless reddish mass much like that of a granuloma from a ruptured chalazion. I. E. Gaynon.

Jébéjian, R. **Local penicillin therapy in trachoma.** Ann. d'ocul. 181:359-364, June, 1948.

Seventeen children between the ages of 7 and 12 years who had recent bilateral trachoma were given local penicillin therapy. Small discs containing 250 units were instilled in both eyes twice daily. At the end of two months, 5 were considered cured, 7 greatly improved and 5 only slightly improved or not at all. Three months later the results were practically the same. It is a question whether the apparently favorable results which followed local penicillin in such small doses were due to its action on the causative virus or on secondary bacterial invaders.

Chas. A. Bahn.

Kronenberg, Bernard. **The use of placental extract in the treatment of herpetic keratitis and superficial punctate keratitis.** Am. J. Ophth. 31:1101-1105, Sept., 1948.

Lindsay-Rea, R. **Various forms of conjunctivitis and their treatment.** Medical Press 220:7-8, July 7, 1948.

The treatment of ophthalmia neonatorum, catarrhal, phlyctenular and angular conjunctivitis is discussed. Penicillin (2,500 units per cc.) is recommended for the first two. Calomel powder, yellow oxide of mercury ointment and general care, are advised for the phlyctenular type. Zinc sulfate is specific for angular conjunctivitis. (2 figures.) I. E. Gaynon.

Marín-Amat, Manuel. **The operation of choice for pterygium.** Arch. Soc. oftal. hispano-am. 8:615-621, June, 1948.

The author advises tearing the head of the pterygium from its bed, dissecting the episcleral tissue at the limbus with a fine bistoury, excising the body of the pterygium with straight fine scissors as far as the semilunar fold, and covering the raw surface with conjunctiva brought down from each side. The multiple fine silk sutures that close the conjunctival wound include the episclera, so as to anchor the conjunctiva. The sutures are removed on the ninth or tenth day. The author asserts that tearing the head of the pterygium from the cornea affords a more complete removal than dissection. (5 figures.)

Ray K. Daily.

Mariotti, Lorenzo. **The Weil-Felix reaction in trachoma.** Ann. di ottal. e clin. ocul. 73:302-310, May, 1947.

On the basis of experiments with carefully selected patients and controls so as to avoid errors that may have misled other investigators, Mariotti concludes that the Weil-Felix reaction is of no practical value in the diagnosis of trachoma. While not denying that trachoma may be a rickettsiosis, he finds no reliable confirmatory evidence in this reaction. (3 tables, bibliography.)

NEWS ITEMS

Edited by DONALD J. LYLE, M.D.
601 Union Trust Building, Cincinnati 2

News items should reach the editor by the 12th of the month

DEATHS

Dr. James Cheston Ogden, Long Beach, California, died May 25, 1948, aged 45 years.

Dr. George Elmer Strout, Minneapolis, Minnesota, died May 10, 1948, aged 75 years.

MISCELLANEOUS

TORONTO REFRESHER COURSE

The University of Toronto, faculty of medicine, announces a refresher course in the combined subjects of practical ophthalmology and otolaryngology from January 24 to January 29, 1949.

The course will be so arranged that the operative procedures and bedside conferences of the one specialty will be held in the mornings and the didactic conferences or lectures in the afternoons. The reverse of this procedure in the other specialty will make it possible to pick whatever subjects may be of interest to each applicant.

Guest speakers will give lectures and clinics in both subjects of the course. The fee will be $60.00. The course will be given for a minimum of 10 students and a maximum of 20 students. Application should be made to the Medical Office, University of Toronto. The closing date is November 30, 1948.

ORTHOPTIC TECHNICIANS PROGRAM

The seventh annual meeting of the American Association of Orthoptic Technicians was held at the Palmer House, Chicago, October 11th and 12th. Among the papers and discussions presented were: "The Binocular Reflexes," Dr. William C. Owens, Baltimore, Maryland; "Some Practical Aspects of Fusion," Miss Mary E. Kramer, Washington, D.C.; "Divergent Squint—Orthoptic Treatment," Miss Alice L. McPhail, New York City; "Accommodative Convergent Squint—Orthoptic Treatment," Miss Georgia Claussen, Santa Barbara, California; "Blindspot Mechanism in Squint," Dr. Kenneth C. Swan, Portland, Oregon; "Functional Treatment of Orthoptics," Mrs. Jeanie G. Haydock, Cincinnati, Ohio; "Problem Cases," Miss Anita Bargmann (leader), Buffalo; "The Handling of the Amblyopic Patient," Dr. Maynard C. Wheeler, New York City, with discussion by Miss Elizabeth Jackson, Erie, Pennsylvania; "The Learning Process in Orthoptics," Miss Julia Lancaster, San Francisco, California, with discussion by Dr. Peter C. Kronfeld, Chicago; "Degrees of Correction per Millimeter of Surgery," Dr. Richard G. Scobee, St. Louis, with discussion by Dr. Wendell L. Hughes, Hempstead, Long Island.

CAROLINAS POSTGRADUATE COURSE

Taking part in the ophthalmic program of the postgraduate course in ophthalmology and otolaryngology, sponsored by the North Carolina Eye, Ear, Nose, and Throat Society and the South Carolina Society of Ophthalmology and Otolaryngology, at Charleston, September 13th to 16th, were the following guest speakers: Dr. James E. Lebensohn, Chicago, who gave lectures on "Problems of Presbyopia," "Techniques of Manifest Refraction," and "Recent Advances of the Physiology of Vision." Dr. Eugene M. Blake, New Haven, Connecticut, spoke on "Intraocular Foreign Bodies with Illustrated Cases," "Constitutional Factors in Chronic Glaucoma," and "Etiology and Nonoperative Treatment of Senile Cataract." Dr. William C. Owens, Baltimore, presented papers on "Some Aspects of Cataract Surgery," "Analysis and Treatment of Strabismus," and "Treatment of Ptosis." Dr. Harold W. Brown, New York, spoke on "Diagnostic Procedures in Measurement of Ocular Muscle Deviations," "Operative and Nonoperative Treatment of Heterophorias," and "Surgical Management of Heterotropias." Dr. J. B. Workman, Columbia, South Carolina, presented a paper on "Nutritional Retrobulbar Neuritis."

FOUNDATION FOR VISION PLANS

At the Foundation for Vision meeting, at Boston on September 27th, it was decided to repeat the course in basic subjects of ophthalmology under the auspices of the Ophthalmological Study Council in 1949 at Portland, Maine. This course will be known as The Lancaster Course in honor of Dr. Walter B. Lancaster who organized and directed it during the past three years. Dr. Lancaster resigned as director and will be succeeded by Dr. Parker Heath, clinical professor of ophthalmology in charge of graduate instruction at Harvard University.

The foundation is also planning to continue the training course for blind children and their mothers originally organized by the late Dr. Theodore L. Terry. The project is to be known as The Terry Center for Visually Handicapped Children.

ESTELLE DOHENY LECTURE

Dr. Cecil S. O'Brien, professor of ophthalmology at the State University of Iowa College of Medicine, delivered the Estelle Doheny Eye Foundation Lecture on "The Surgical Treatment of Strabismus" at the Los Angeles County Medical Association Building in Los Angeles on November 8th. The first of these annual lectures presented by the

Estelle Doheny Eye Foundation in Los Angeles was delivered by Dr. Alan C. Woods, professor of ophthalmology at Johns Hopkins University and director of the Wilmer Institute, on December 17, 1947.

University of California course

The University of California Medical School is planning a postgraduate course in ophthalmology to be given September 12 through 16, 1949. This will be a continuation of the courses offered in 1947 and 1948 and is intended for specialists.

Societies

Minnesota Academy officers

Officers of the Minnesota Academy of Ophthalmology and Otolaryngology elected for 1948-49 are: president, Dr. A. D. Prangen, Rochester; 1st vice-president, Dr. L. Tilderquist, Duluth; 2nd vice-president, Dr. Joseph Garten, Minneapolis; secretary-treasurer, Dr. Frank Adair, St. Paul; chairman-of-council, Dr. Hugo Bair, Rochester.

New York officers

Dr. Wendell L. Hughes is chairman, and Dr. Isadore Givner, secretary, of the Eye Section of the New York Academy of Medicine.

Reading meeting

The 83rd meeting of the Reading Eye, Ear, Nose, and Throat Society was held September 15th. The speaker was Dr. Lewis K. Elfman, chief in otolaryngology, Philadelphia General Hospital.

South Carolina officers

Newly elected officers of the South Carolina Society of Ophthalmology and Otolaryngology are: president, Dr. Pierre G. Jenkins, Charleston; vice-president, Dr. Murdock H. Walker, Sumter; secretary-treasurer, Dr. Roderick Macdonald, Rock Hill.

West Virginia meeting

The West Virginia section of the Southeastern Surgical Society met on September 4th in Huntington, with Dr. Albert C. Esposito presiding, to hear Dr. Arthur M. Culler, professor and chairman of the department of ophthalmology, Ohio State University, College of Medicine, Columbus, read a paper on "The Cross-Eyed Child."

Mexican society lectures

Dr. Adalbert Fuchs gave a course of 20 lectures on the pathology of the eye from June 24th to July 13th for the Sociedad Mexicana de Oftalmologia.

Brooklyn society officers

At the 105th regular meeting of the Brooklyn Ophthalmological Society, Dr. Adalbert Fuchs presented a paper on "Early Diagnosis of Tumors of the Fundus" and Dr. Ralph I. Lloyd led the discussion. The present officers of the Brooklyn society are: Dr. Frank E. Mallon, president; Dr. Mortimer A. Lasky, vice-president; Dr. Louis Freimark, secretary-treasurer; and Dr. George A. Graham, associate secretary-treasurer.

Sociedad de Oftalmologia del Litoral

The Ophthalmological Society of the Litoral, Rosario, Argentina, has elected the following officers for the term from August, 1948, to August, 1950: Dr. Juan Manuel Vila Ortiz, president; Dr. Juan Maggi Zavalía, vice-president; Dr. Máximo Carlos Soto, secretary; Dr. Benito Bianco, treasurer; Dr. Luis Woelflin, Dr. René Bazet, Dr. Mario Zurbriggen, and Dr. Juan P. Alliani, directors.

Sociedade de Oftalmologia de Minas Gerais

The Ophthalmological Society of Minas Gerais, Brazil, has elected the following officers; President, Dr. C. Laborne Tavares; vice-president, Dr. Odilon Alves; secretary, Dr. Creso Barbi; treasurer, Dr. Angelo Laborne Tavares; historian, Dr. Antonio Isidoro.

Instituto Penido Burnier

The Medical Association of the Instituto Penido Burnier, Campinas, announces the election of the following officers: Dr. João Penido Burnier, president; Dr. Gabriel Pôrto, 1st secretary; Dr. Roberto Barbosa, 2nd secretary; Dr. Leôncio de Souza Queiroz, historian and treasurer; Dr. Guedes de Melo Filho, Dr. F. J. Monteiro Sales, and Dr. José Martins Rocha, directors.

THE FASCIA OF THE ORBIT*

ITS ANATOMY AND CLINICAL SIGNIFICANCE

RICHARD G. SCOBEE, M.D.
Saint Louis, Missouri

Much of the anatomy of the normal fascia of the orbit has been well known for more than a century and yet the average ophthalmologist is still not entirely familiar with certain portions of it. Various subdivisions of this fascia play a prominent role in the success or failure of the surgical treatment of heterotropia. Some parts may contain developmental anomalies which probably play an important role in the etiology of heterotropia.[1] It would, therefore, seem worthwhile to review and summarize the known facts about the fascia of the orbit and at the same time emphasize the clinical significance of certain sections.

On any map of the nation's highways, each road has a different number, the equivalent of a name. The same road is also part of the system of highways of the nation and connects with other highways which also have numbers or names. Each road is an integral part of the highway system. In similar fashion, many subdivisions of the fascia of the orbit bear different names but nevertheless all comprise the fascia of the orbit and any one part connects with one or more other parts. Since the fascia of the orbit is more or less continuous, in a sense, the apex of the orbit is as good a place as any to begin the consideration.

* From the Department of Ophthalmology, Washington University School of Medicine, and the Oscar Johnson Institute. This study was made under a contract with the Office of Naval Research as Project N6onr-202, Task Order I, NR 141-022.

THE DURA MATER

The intracranial portion of the optic nerve is sheathed in the meninges. As the nerve passes through the optic canal at the apex of the orbit, the meninges are rather closely pressed around it. The orbital portion of the nerve is much more loosely ensheathed.

At the point where the dura mater emerges from the canal of the optic nerve at the apex of the orbit, it divides into two layers. The inner layer continues along the optic nerve to the junction of that structure with the eyeball. The outer layer spreads out to cover the bony walls of the orbit and become known as the *periorbita.*

The function of the periorbita is similar to that of periosteum elsewhere. At the anterior end of the orbit—the orbital margin—the periorbita is confluent with the periosteum covering the bones of the face; at the rim of the orbit where these two differently named but similar layers of fascia meet, they become thickened to form a ridge known as the *arcus marginale.*[2]

This ridge of fascia marks the exact line of the orbital margin and from it arises the *septum orbitale* of the eyelids. This latter structure is also a part of the fascia of the orbit.

THE ANNULUS OF ZINN

Returning to the apex of the orbit where the dura mater of the optic nerve divides into an outer layer—the periorbita—and an

inner layer—the dura of the orbital portion of the optic nerve—there is a roughly circular tendinous cord lying between the two layers immediately after they have become distinct and separate at the apex of the orbit. This tendinous cord is known as the *annulus of Zinn* and it is rather intimately fused with both the periorbita and the dura of the optic nerve. The annulus has a very interesting history.

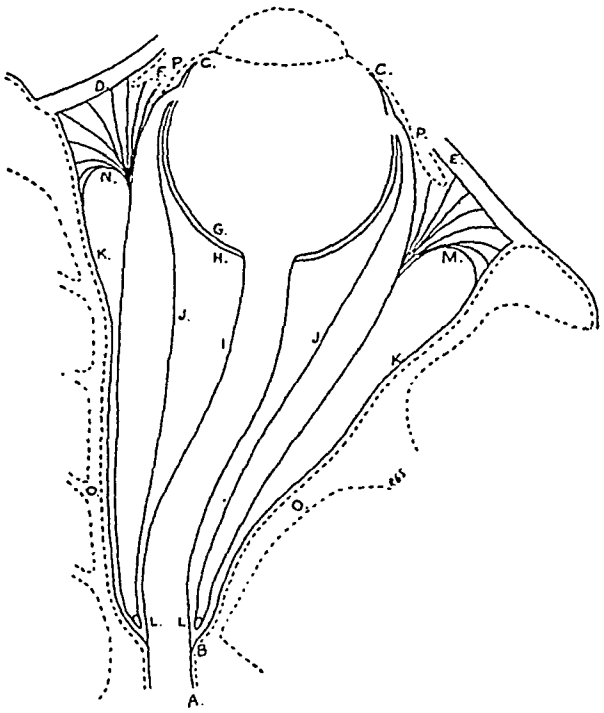

Fig. 1 (Scobee). Diagram showing only the fascia of the orbit (in solid lines). Bone, cornea, and conjunctiva are represented in dotted lines.

A. Meninges of optic nerve in optic canal.
B. Point of division of dura mater into periorbita and optic nerve sheath.
C. Point of fusion of Tenon's capsule with sclera.
D. Medial palpebral ligament.
E. Lateral palpebral ligament.
F. Lacrimal caruncle.
G. Visceral layer of Tenon's capsule.
H. Parietal layer of Tenon's capsule.
I. Dural sheath of optic nerve.
J. Muscle sheath.
K. Periorbita.
L. Annulus of Zinn.
M. Check ligament of lateral rectus muscle.
N. Check ligament of medial rectus muscle.
O. Bone of orbital wall.
P. Conjunctiva.

It is apparently not generally known that Zinn[3] described ". . . a ligament common to the inferior, internal, and external recti" only. He did not describe the entire circular structure as we know it today.

Sappey[4] described Zinn's structure as ". . . a fibrous cord which is attached to a very small fossa situated beneath and external to the optic foramen. This cord speedily divides into three slips—a middle, which goes to the inferior rectus; an inner, to the internal rectus; and an external, to the external rectus. Of these three bands the middle is the largest."

Lockwood[5] added to Sappey's remark that ". . . it may be added that the fasciculus, which belongs to the external rectus, is prolonged up the posterior border of the muscle, and ends by blending with the origin of the superior rectus."

It is obvious that the structure which Zinn described was in reality only the lower half of what is now referred to as the annulus of Zinn. The technique of dissection in the time of Zinn was well standardized in the case of the orbit and consisted in an approach to the orbital contents from above, the roof having been removed.

This external view of the muscle cone from above, the fat having been dissected away, revealed the fibrous appearing orbital surfaces of the superior rectus and the upper halves of the medial and lateral recti; from this approach, these fibrous outer surfaces of the muscles mentioned appeared to blend intimately with the dura mater of the optic nerve.

The technique then called for division of the superior rectus at its origin, followed by division of the optic nerve within its bony canal; both structures were next lifted upward and pushed aside. This maneuver exposed the inner surfaces of the medial and lateral rectus muscles and of the inferior rectus. From this aspect, the tendinous band across the inferior half of the optic foramen was exposed as the obvious point of origin of the three muscles listed.

It remained for Lockwood[5] to obtain a frozen orbit and divide it in a plane passing through the center of the pupil and the center of the optic foramen. When the inferior surface of this upper half of the orbit was inspected and the optic nerve pulled from its bed in the canal, the inner surfaces of the superior rectus as well as of the superior halves of the medial and lateral rectus muscles were then exposed to view and a tendon similar to the one Zinn had described below was easily visualized. This upper tendon has since been correctly called the *upper tendon of Lockwood* while the lower one is known as the *lower tendon of Zinn,* and the two together make up what is somewhat incorrectly but widely known as the *annulus of Zinn.*

The point of nomenclature here is one of purely academic interest and yet the story invites attention because it shows how often inaccuracies have crept into medical literature with the passage of time. A prime example of such an inaccuracy is the widely held notion that Helmholz invented the ophthalmoscope when it was in fact Babbage, an English mathematician, who first conceived the instrument.[6]

The capsule of Tenon

Consider now the dura which ensheathes the optic nerve in its orbital course. This membrane fuses with the fascial capsule which encases the globe—the *capsule of Tenon.*

Tenon[7] discovered the capsule which bears his name in 1803 and reported it in 1806. Surprisingly enough, or perhaps not so surprisingly after all, it was then forgotten for many years and Hyrtl[8] said that Malgaigne[9] finally brought it again to notice but called it by the name of the *orbital aponeurosis.*

In 1841, Bonnet[10] wrote an elaborate description of it and emphasized its surgical importance; his work was so well received that many began to speak of the structure as the capsule of Bonnet. In the same year, Ferrall[11] published a paper on the *tunica vaginalis oculi* in which he rediscovered the original capsule of Tenon; quite obviously, he was familiar with the work of neither Tenon nor Bonnet.

Since that time, many have described the capsule of Tenon, prompting Dwight[12] to observe somewhat cynically that ". . . the complications of this membrane are limited only by the perverted ingenuity of those who describe it."

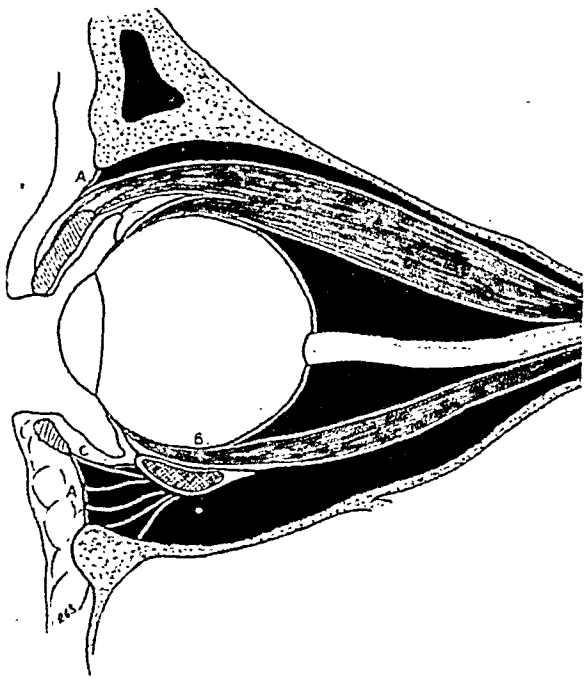

Fig. 2 (Scobee). Schematic vertical section through the orbit. The extensions of the suspensory ligament of Lockwood, particularly the one to the inferior tarsal plate (C), are shown, as is the suspensory ligament (B). The orbital septum is shown (A) superiorly and inferiorly. Note the close association of the levator and the superior rectus throughout most of their course.

The capsule of Tenon encases the globe from the limbus to the optic nerve, has a yellowish color and a closely matted appearance. The anterior third of the capsule is closely related to the bulbar conjunctiva under which it lies but from which it may be easily separated to within about 2 mm. from the limbus. In vertical sections, the anterior

portion of the capsule seems to blend with the superior and inferior conjunctival fornices. At these fornices, the capsule divides into two portions; one goes to the tarsal plate and the other runs to the sclera with the bulbar conjunctiva.

The middle third of the capsule is pierced by the six oculorotary muscles passing toward their scleral insertions. At the point where each penetrates the capsule, a prolongation of the capsule is sent backward along each muscle—*the muscle sheaths.*

The posterior third of the capsule is thinner than the anterior and middle thirds and is in contact with and loosely adherent to the orbital fat.

Whitnall[2] is of the opinion that connective tissue strands, hardened by alcohol or formalin and isolated by dissection from fat and neighboring structures, assume in many regions ". . . unwarrantable distinctions as membranes, ligaments, or capsules." He believes that if a firm body, such as the globe, revolves against a cushion of fatty tissue, the fat will be pressed away and the connective-tissue meshwork supporting it will be condensed into a membranoid surface. He states that this is what has happened in the case of the capsule of Tenon, agreeing that its posterior surface is connected with the meshwork of orbital fat, and that even in his most careful dissections, the posterior aspect of the capsule of Tenon is ragged and perforate. The earlier investigators, however, specifically stated that they used either fresh specimens or frozen ones rather than those which had been immersed in fixatives; hence Whitnall's objections to modern techniques would not seem applicable to the works of the older anatomists.

Schwalbe[13] described the capsule of Tenon as being divided into a visceral and a parietal layer. Of the two, the outer or parietal layer is the thicker and more easily defined and is the portion usually described as the capsule of Tenon. It is also referred to by some as the *fascia bulbi.*

The visceral layer, which covers the sclera and the region about the tendinous insertions of the oculorotary muscles, is thin and delicate. The space between the two layers is known as the *space of Tenon* or the *suprascleral lymph space of Schwalbe.* Delicate connective tissue fibers are found extending directly and obliquely across this space between the two layers.

In tenonitis, Lockwood[5] believed that it was the visceral layer of the capsule which was primarily involved, since the visceral layer is very similar to episcleral tissue.

There is universal agreement that the capsule of Tenon posteriorly is rather firmly adherent to the sclera around the point of exit of the optic nerve and that it fuses with the dural sheath of the nerve at their junction. Lockwood reported that the parietal layer of the capsule is composed of white fibrous tissue and elastic tissue while the visceral layer is mostly loose areolar tissue. Bonnet referred to the visceral layer as *subconjunctival fascia.*

Where the oculorotary muscles enter the capsule on the way to their scleral insertions, there are six visible openings. Each muscle is lightly attached to its own opening by the visceral layer of the capsule of Tenon. Lockwood described a band of fibers embedded in the capsule crossing the posterior edge of each opening and called these bands the *intracapsular ligaments* (fig. 3). There have been some interesting suppositions about these structures.

Ferrall[11] supposed that the intracapsular ligaments acted as pulleys over which the muscles worked, but this seems very doubtful. Whitnall[2] flatly stated that ". . . there are no pulley bars or intracapsular ligaments, and no need for them."

Lockwood,[5] however, described the intracapsular ligaments and said of those of the medial and lateral rectus muscles that their inferior ends were attached to the suspensory ligament (of Lockwood) and thus held firmly in place. He had a particularly interesting observation about the intracapsular ligament of the superior rectus, saying that

". . . it is quite lengthy, its inner extremity being fastened to the trochlea while the outer is attached to the wall of the orbit just above the lateral rectus muscle. Its oblique direction alters decidedly the pull of the tendon of the superior rectus which must turn nasally after passing through its opening in the capsule to reach its insertion in the sclera."

In speaking of the inferior oblique, Lockwood wrote that ". . . its aperture is just behind and lateral to that for the inferior rectus in the capsule, but it is separated from it by the intracapsular ligament which the suspensory ligament forms for that muscle and, in addition, by a small oblique band of fibers which cross the upper surface of the

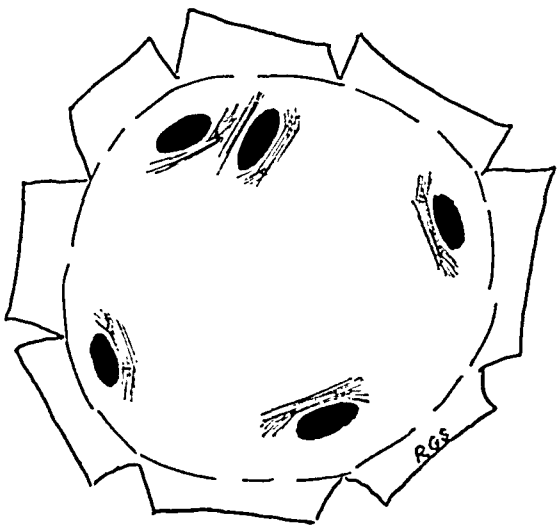

Fig. 3 (Scobee). Drawing showing the inside of Tenon's capsule after the globe has been removed. The points of entrance of all of the oculorotary muscles except the superior oblique are shown as black holes. The thickenings at the posterior margin of each hole are the intracapsular ligaments described by Lockwood.

suspensory ligament." Whitnall[2] is the only investigator who denies the existence of the intracapsular ligaments.

Intermuscular Membrane, Check Ligaments and Muscle Sheaths

It has been previously stated that the middle third of the capsule of Tenon is perforated by the six oculorotary muscles in their course toward their scleral insertions. At the point where each muscle passes through the capsule, the parietal or outer layer is reflected backward along each muscle as a sheath—*the muscle sheath.*

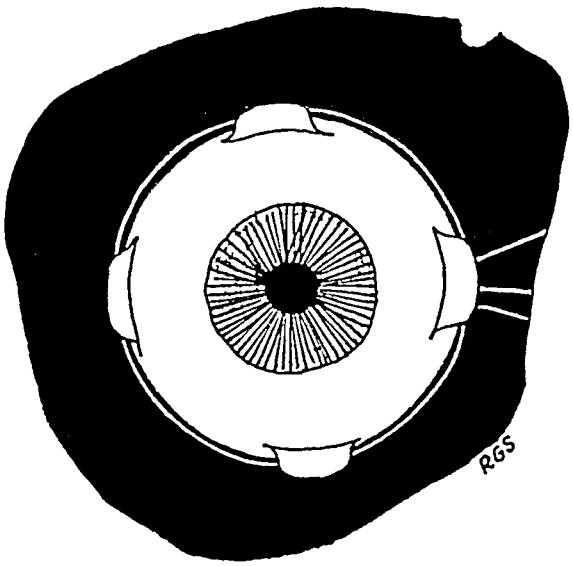

Fig. 4 (Scobee). Diagram showing the intermuscular membrane running between the four rectus muscles. The muscle sheaths are not clearly shown but the three normal check ligaments of the medial rectus muscle are shown fanning out from muscle sheath to periorbita.

According to some investigators, the sheath of each muscle extends all the way back to the point of origin of the muscle, although it is quite true that the sheaths in the posterior half of the orbit become quite thin and difficult to distinguish.

The portion of the fascia of the orbit forming the muscle sheaths is known as the *muscular fascia* and, in addition to ensheathing each muscle completely, the muscular fascia stretches as a membrane between the adjacent margins of the rectus muscles.

This latter structure is known as the *intermuscular membrane* and is usually thickest between the superior and lateral rectus muscles. According to Whitnall[2] the backward extension of the intermuscular membrane is usually greatly exaggerated and practically only extends for a short distance behind the globe.

INTERMUSCULAR MEMBRANE

Poirier[14] described the intermuscular membrane in some detail in 1912 and stated that it separated the fat of the orbit into two layers, one central and the other peripheral, and controlled to a certain extent the progress of any infiltration which might occur in that region. Whitnall objected to Poirier's work on technical grounds and his idea on

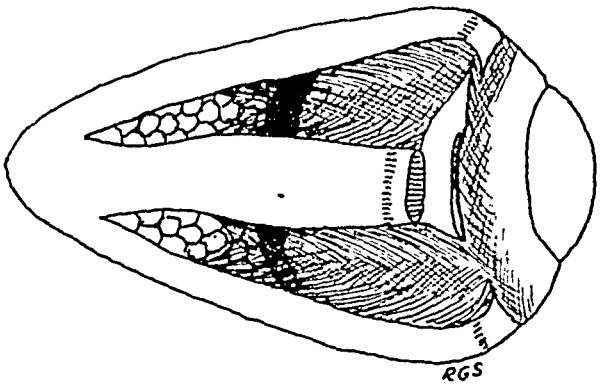

Fig. 5 (Scobee). Drawing showing the method of Jameson in performing what he called "vertical capsulotomy" on the intermuscular membrane. The muscle has been severed from its insertion and is retracted slightly. The intermuscular membrane has been cut vertically from the insertion of the muscle up to the margin of the insertion of the superior rectus muscle.

the posterior limits of the intermuscular membrane has just been cited.

Butler[15] reported a patient with pus confined to the muscle cone; there were proptosis, pain, and rigors but three incisions for orbital drainage failed to locate any purulent material. It was not until enucleation was performed that pus was encountered and it was found within the muscle cone, confined there by the intermuscular membrane. It is perfectly true that in thin and feeble subjects, however, the membrane may be poorly delimited and difficult to demonstrate.

Jameson[16] was one of the first to mention the clinical significance of the intermuscular membrane in the surgical treatment of heterotropia. In performing his operation of recession, Jameson did what he called a "vertical capsulotomy" in which he incised the intermuscular membrane vertically from the superior margin of the medial rectus at its insertion to the superior rectus and from the inferior margin of the medial rectus downward to the inferior rectus.

Lancaster[17] pointed out that when a muscle's tendon is cut at its insertion into the sclera, the muscle and tendon are not left free and unattached to retract indefinitely into the orbit. On the contrary, the cut tendon retracts only from 3 to 5 mm. or even less because the capsule of Tenon which envelops the muscle is attached to the sclera at about the same distance from the cornea as the tendon insertion, and its connection with the muscle (that is, the intermuscular membrane) is sufficiently firm and intimate to serve as a secondary attachment for the muscle.

If the intermuscular membrane is not divided, one gets nowhere near the maximum effect possible from recession of a muscle. The idea of the recession operation is to reduce the mechanical advantage of a muscle by reinserting it posteriorly on the globe and thus reducing not only its tension but also its arc of contact. If there are broad secondary attachments of the muscle, the mere recession of its tendinous insertion alone, leaving the intermuscular membrane intact, will accomplish but little in comparison with what the operation might do potentially.

The direction in which the intermuscular membrane is cut in the recession operation has a definite bearing upon the amount of correction which may be obtained.[1] As has been mentioned, Jameson sectioned the intermuscular membrane vertically. Even more correction will be obtained if the membrane is sectioned parallel to and within a millimeter or two of the borders of the muscle being recessed, and the membrane should be divided as far posteriorly as it extends.

The intermuscular membrane may have an anomalous development in certain parts which seems to play a definite role in the etiology of heterotropia.[1]

For example, in the patient with intermittent exotropia, it is not at all an uncommon finding for the intermuscular membrane between the lateral rectus and inferior rectus muscles to be markedly thickened and very tough; such an anomaly has the effect of giving the lateral rectus a much wider and heavier attachment than is normal and increasing the action of the muscle to that extent. It is extremely important to divide this thickened portion of the intermuscular membrane completely from the lateral rectus muscle when operating on patients with intermittent exotropia.

The muscle sheaths of all six of the oculorotary muscles have offshoots from their outer or orbital surfaces which become attached either directly or indirectly to the periobita, or to some other portion of the fascia of the orbit. These extensions of the muscle sheaths are known as *check ligaments,* but have also been called *fascienzipfel* or *ailerons.*

Check Ligaments

It is interesting that Tenon[7] believed that the check ligaments altered the direction of the muscles to the extent that, during their contraction, they would not exert pressure upon the globe. Cruveilhier[18] raised doubts about this point, and Lockwood[5] pointed out, quite logically, that the check ligaments of the horizontal rectus muscles, for example, leave the wall of the orbit almost exactly opposite the equator of the globe and run backward nearly half an inch before becoming continuous with the muscle sheaths; this union is far behind the place where the arc of contact of the muscles begins so that the check ligaments would be quite inefficient in preventing pressure upon any part of the globe during contraction of the muscle from whose sheath they arise.

All investigators beginning with Tenon have unanimously agreed on the primary action of the check ligaments in preventing or checking undue contraction of the muscle from whose sheath they spring.

A point that does not seem to be recognized at all, however, is that the check ligaments may act to check motion in *two* directions,[19, 1] particularly if they are unusually thick or have some other anomalous character.

Not only may the check ligaments of the medial rectus muscle prevent excessive contraction of that muscle and thus prevent excessive adduction of the eye, but abnormalities of the check ligaments of this same muscle may also prevent its free relaxation when its antagonist, the lateral rectus, is contracting and thus prevent free abduction of the globe as well. Limitation of motion thus produced may well be an important underlying anatomic factor in the etiology of heterotropia.[1]

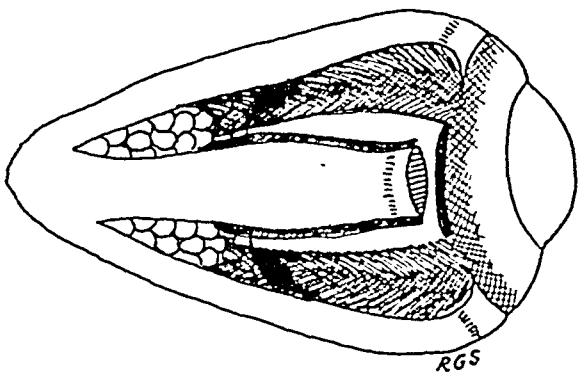

Fig. 6 (Scobee). The intermuscular membrane severed horizontally from the muscle insertion to the posterior extremity of the membrane. It has been divided parallel to the borders of the muscle above and below at a point between 1 and 2 mm. from the muscle borders. This procedure allows a recession to gain its maximum effect.

There are three main types of anomalous check ligaments which are found very commonly in heterotropia:[1] (1) Extra and thickened check ligaments, (2) posterior check ligaments, and (3) fused check ligaments. Any of these types may prevent free abduction of an eye when present on the medial rectus muscle, or free adduction when on the lateral rectus muscle. They must be sectioned at operation if the surgical therapy of heterotropia is to be consistently successful and if the surgeon is to

get the maximum effect desired from the operation of recession.

The check ligaments of the horizontal rectus muscles are not a single simple sheet of fascia as was once thought, but instead there are several sheets fanning out from the muscle sheath to reach insertions in the periorbita. When the check ligaments of the medial rectus, for example, are put on a stretch at the time of surgery, they remind one of the pages of a book fanning out from the binding when the covers of the book are purposely held open with back to back.[19]

The greatest width of the check ligaments anteroposteriorly of the lateral rectus is between 6 and 8 mm. while the distance from the anterior end of their orbital insertion to their point of union with the sheath of the muscle posteriorly measures 18 to 20 mm. The point of greatest thickness lies at a distance of from 3 to 6 mm. from the orbital insertion.

These check ligaments are not particularly dense but are composed of a number of bundles of parallel fibers; the fasciculi are separated by small adipose tissue masses, little veins, and lobules of the lacrimal gland. The tiny veins just mentioned are the source of the relatively profuse bleeding encountered in cutting the check ligaments of this muscle when the surgeon has been careful to avoid cutting the anterior ciliary artery until it has been compressed in the suture placed in the tendon of this muscle.

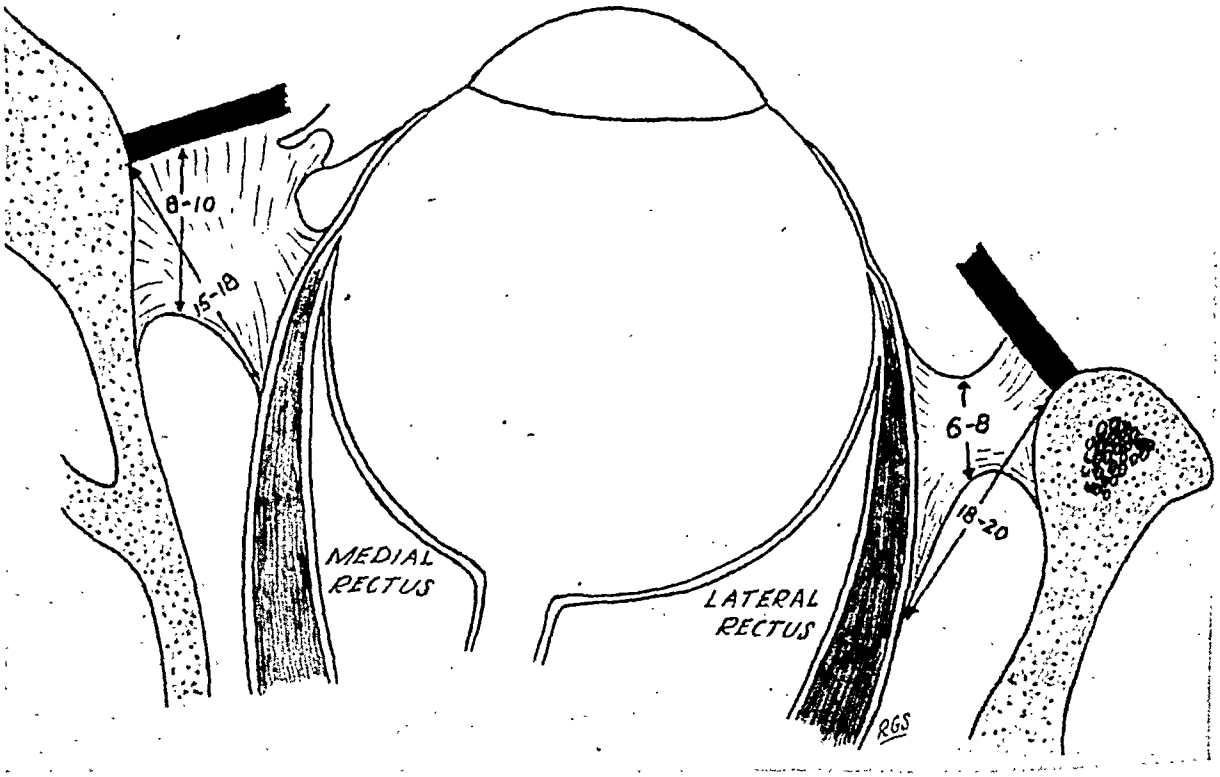

Fig. 7 (Scobee). Diagram showing dimensions of the check ligaments of the horizontal rectus muscles as seen from above.

The check ligaments of the lateral rectus muscle are more easily demonstrated than those of the medial rectus. They form a wedge-shaped structure with the base of the wedge fastened by a vertical attachment to the periorbita over the malar bone, dorsal to the lateral palpebral ligament, in an area about 6 or 7 mm. long; the apex of the wedge is continuous with the sheath of the lateral rectus.[20]

In this posterior two thirds, the check ligaments of the lateral rectus correspond closely with the structure of the muscle

sheath, while their anterior third often contains plain muscle fibers which have been repeatedly demonstrated by many investigators[20] since Sappey[4] first described them. Most of the fibers of the check ligaments of the lateral rectus are elastic tissue.[5]

The check ligaments of the lateral rectus muscle, in addition to their insertion over the orbital tubercle on the lateral wall of the orbit, are also attached to the posterior face of the lateral palpebral ligament (which is also inserted into the orbital tubercle) and into the conjunctiva of the lateral fornix.

The check ligaments of the medial rectus muscle present a similar triangular formation to those of the lateral rectus[20] and are attached to the medial wall of the orbit over the lacrimal bone just behind the posterior lacrimal crest. They are also attached to the septum orbitale behind the pars lacrimalis muscle of Müller, to the lacrimal caruncle, and to the conjunctiva in the medial fornix.

These check ligaments are wider than those of the lateral rectus muscle (8 to 10 mm. as compared with 6 to 8 mm.), but their thickness of 1.0 to 1.5 mm. is less than that of the ligaments of the lateral rectus. They are shorter (15 to 18 mm.) than those of the lateral rectus (18 to 20 mm.).

Sutton[20] described many hairlike fibrous projections from the check ligaments of the medial rectus which unite with the capsules of the adipose masses in that region. There are no interstices similar to those found in the lateral rectus check ligaments. Plain muscle fibers have also been demonstrated in the anterior third of these check ligaments. According to Motais, the check ligaments of the medial rectus have more elastic fibers than do those of the lateral rectus.

Any of the anomalies of the check ligaments previously mentioned may play an important role in the etiology of heterotropia. It is, therefore, essential that the check ligaments be divided from the muscle sheath when a recession operation is done if the surgeon is to get the full and proper effect from this procedure.[19, 1]

The fact that the check ligaments of the medial rectus muscles are attached to the caruncle, to the medial conjunctival fornix, to the posterior surface of the medial palpebral ligament, and to the periorbita of the medial wall of the orbit has been mentioned. If the full effect of a recession operation is to be gained, all of the check ligaments must be severed.

In the past, various writers have strenuously objected to cutting the check ligaments on the grounds that in the case of the medial rectus such a procedure leads to retraction of the caruncle. Quite the opposite is true and for obvious mechanical reasons.[1] The check ligaments prevent excessive contraction of the muscle from whose sheath they arise; this is to say that they prevent undue shortening of the muscle.

A recession operation is the equivalent in one respect to a shortening of the muscle in contraction in that either event places a certain amount of stress upon intact check ligaments. When the check ligaments of the medial rectus muscle are put under stress, since they are attached to the caruncle, there results a retraction of the caruncle. If, however, the check ligaments of the muscle are divided before the muscle is recessed, no strain is placed upon the check ligaments and hence there is no retraction of the caruncle.

The facts speak for themselves and are proved by a series of over 120 patients[1] with esotropia in whom the check ligaments of the medial rectus muscle have been completely severed from the sheath of the muscle prior to a recession of that muscle; there has been not a single instance of retraction of the caruncle postoperatively in the entire series.

A word of caution must be inserted about exercising care when cutting check ligaments from the muscle sheath. This procedure does not involve stripping the sheath from the muscle to leave the latter bare and exposed; it merely entails cutting the check ligaments close to the point where they origi-

nate from the sheath. There are serious objections to stripping a muscle of its sheath because adhesions invariably form between bare muscle and any adjacent tissue and this is very undesirable.

Ledouble[21] first described a fasciculus of striated muscle in the check ligaments of both horizontal rectus muscles and said that they were fairly frequent in occurrence and were presumably offshoots of the muscles themselves. Such offshoots are not uncommon in patients with heterotropia and may play a role in the etiology of the heterotropia.[1]

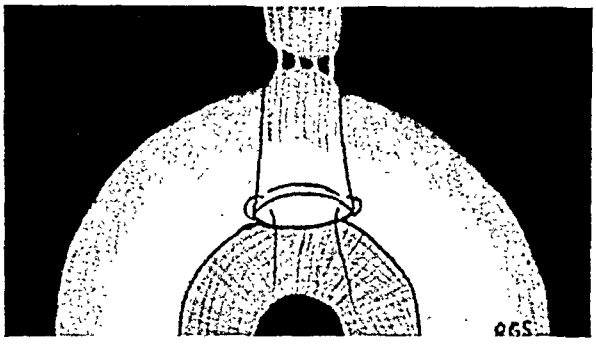

Fig. 8 (Scobee). Schematic drawing of the eyeball showing only the superior rectus severed from its insertion and pulled forward and downward by means of sutures. The levator is shown above and the usual four dentate connections between the two muscles can be seen put on a stretch by this maneuver.

Muscle sheaths

The relations of the sheaths of the rectus muscles are all of the same type; at the point where muscle tendon is inserted into sclera, the sheath passes from the internal or ocular surface of the muscle backward as part of the middle third of the capsule of Tenon. The sheath passes from the external or orbital surface forward to find attachment partly into the fornix of the conjunctiva and partly into the sclera near the limbus. There are certain modifications in the case of each individual rectus muscle. The relations of the superior rectus, for example, are complicated by the presence of the levator.

The muscle sheath of the superior rectus is similar to those of the other recti already mentioned but it has no check ligaments similar to those of the horizontal rectus muscles. Its sheath and that of the levator are rather intimately attached since the two muscles are in close apposition throughout most of their course.

Through its adherence to the levator via their sheaths, the superior rectus gains a form of attachment to the aponeurosis of the levator and to the superior tarsal cartilage in addition to its attachment to the bulbar conjunctiva and the superior conjunctival fornix.

The lateral attachments of the levator to the orbital walls act as check ligaments for that muscle and, according to Cruveilhier,[18] make the tarsal cartilage of the upper lid function like the visor of a helmet. The check ligaments of the levator also function as check ligaments of the superior rectus because of the intimate relationship between the two muscles and furthermore the superior rectus can partially lift the upper lid for the same reason.

If one carefully pulls the superior rectus downward away from the levator, there are usually four fairly thin sheets of fascia running longitudinally between the two muscles, and these sheets, when put on a stretch and viewed anteriorly, have a dentate appearance.

If a recession operation on the superior rectus is to be fully effective, not only must the intermuscular membrane be divided on each side of the muscle as far back as it extends, but the connections between the sheaths of the superior rectus and the levator must be gently divided without stripping either muscle of its sheath and leaving it bare.

If this latter procedure is not done, the effect of a recession will be minimal because the attachments between the superior rectus and the levator will prevent the recessed superior rectus from retracting properly.

Failure to observe this simple precaution is responsible for much of the widespread dissatisfaction with recession of the superior rectus muscle on the grounds that it is a relatively ineffective and always unpredictable procedure. When the operation is properly done, it is neither ineffective nor unpredictable.

The superior oblique in early fetal life has no connection with the wall of the orbit. As the muscle develops, it gradually approaches the wall of the orbit and finally becomes attached to it. In the course of the development, the trochlea is a secondary structure. The attachment of the sheath of the superior oblique to the trochlea is by small sheets of fascia given off both before and after the sheath containing the muscle has passed through the trochlea.[20]

Various authorities disagree about the extent of the muscle sheath of the superior oblique. Lockwood[5] believed that it extended only from Tenon's capsule to the trochlea. Sutton[20] found it extending on backward through the trochlea but did not state how far. Fink[22] found that a recognizable sheath extended some 8 to 10 mm. posteriorly from the trochlea.

Others have stated that it extends about half way backward from the trochlea to the origin of the muscle, while still others claim that it covers the muscle in its entire course from origin to trochlea and from trochlea to the globe. It seems likely that the thick and obvious portion of the sheath runs from the capsule to and through the trochlea and then becomes progressively thinner as it is traced posteriorly until it blends almost imperceptibly with the perimysium.

Berke[23] has effectively demonstrated that the tendon of the superior oblique is intimately attached to its encasing sheath from trochlea to globe by countless tiny trabeculae. If the tendon is divided within its sheath, the cut ends retract a short distance before they are stopped by the anchoring effect of these hundreds of tiny trabeculae.

Because of this fact, Berke has proposed the very effective procedure of intrasheath tenotomy of the superior oblique as a lengthening operation for that muscle in patients in whom it is desired to lessen its action. Gradations of effect may be obtained from the smallest, by simple tenotomy, to the greatest, by actual tenectomy of varying lengths of tendon. The operation is easy to do and is very satisfactory.

The sheath of the inferior rectus is quite similar to that of the other rectus muscles except anteriorly where it divides into two layers: a superior one which joins the capsule of the globe and runs forward to become inserted into the sclera near the limbus, and an inferior layer which is inserted into the posterior border of the sheath of the inferior oblique as well as into the suspensory ligament of Lockwood.

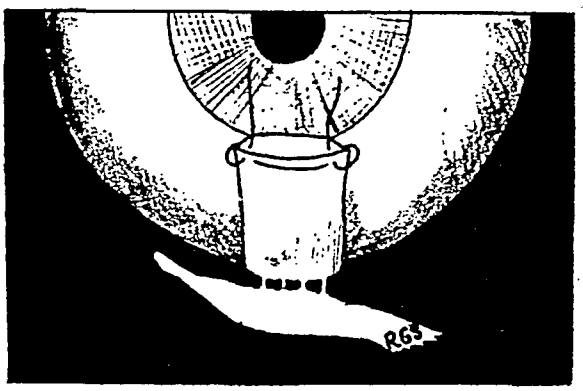

Fig. 9 (Scobee). Schematic drawing of the eyeball showing only the inferior rectus severed from its insertion and pulled forward and upward out of its bed in the suspensory ligament by means of traction sutures. The inferior oblique is represented below and the usual four dentate connections between the inferior rectus and its bed can be seen when put on a stretch by this maneuver.

Once the inferior rectus has passed through its opening in the capsule of Tenon, it runs forward to its insertion lying in a bed formed by the suspensory ligament. If the inferior rectus is lifted carefully upward and out of its bed, it is usual to find four thin sheets of fascia running longitudinally with the muscle and connecting the muscle

sheath to the suspensory ligament; viewed anteriorly when put on a stretch, these have a dentate appearance similar to the same connections found between the superior rectus and the levator.

It is to be emphasized that the sheath of the inferior rectus is attached by fascial sheets only to the suspensory ligament of Lockwood and to the posterior surface of the sheath of the inferior oblique. The bands to these two attachments are the check ligaments of the inferior rectus. Unless they are divided, the recession operation is neither completely successful nor satisfactory.

For many years, one objection to recession of the inferior rectus has been that the procedure leads to retraction or drooping of the lower eyelid. It will be noted that the sheath of the inferior rectus has no direct connection to the tarsus of the lower lid. As will be pointed out in subsequent paragraphs, however, the suspensory ligament of Lockwood is connected to the tarsus of the lower lid and so is the check ligament of the inferior oblique. Thus, the sheath of the inferior rectus has two indirect connections with the lower lid.

If the inferior rectus is recessed and the connections of its sheath with the sheath of the inferior oblique and with the suspensory ligament of Lockwood are not divided, backward tension is placed on both of these structures—tension which is transmitted through them to the tarsus of the lower lid, resulting in retraction or drooping of that lid.

If, however, the sheath of the inferior rectus is divided from its attachments in the operation of recession, no backward tension is created and there is no drooping or retraction of the lower lid.

Again, as in the case of retraction of the caruncle, the simple mechanical facts are obvious and have been proved in a suitable number of cases. Furthermore, unless these attachments of the sheath of the inferior rectus are divided in the operation of recession, the operation will not have its maximum effect and the results will be highly unpredictable, just as in the case of the superior rectus.

As soon as the surgeon stops avoiding the vertical rectus muscles because recession operations on them are "unsatisfactory" and begins to do the operation properly with due regard for the mechanics of the situation, just so much sooner will the surgical therapy of the vertical deviations gain a sound footing on the basis of cases successfully handled.

Ligament of Lockwood

Before considering the sheath and check ligament of the inferior oblique, it would be well to mention the ligament of Lockwood. We shall return to the original work of Lockwood[5] for his own description first. "The suspensory ligament is a band of fibrous tissue stretched, like a sling, from one side of the orbit to the other. The fibers which compose it converge at each end to be inserted into the malar and lacrimal bones; in the middle they diverge to form a shallow cup upon which the eye rests. The widest part of the suspensory ligament is intimately woven with the capsule of Tenon, but not to such an extent as to conceal the identity of its fibers."

Lockwood continued: "The inferior portion of the capsule of Tenon is thickened and has an aperture through which the inferior rectus passes. The posterior part of Tenon's capsule inferiorly is thickest just behind this opening for the inferior rectus and gradually becomes thinner as it passes round the eye; the anterior part looks crescentic and sends a long thin horn backward beneath the inferior rectus, forming the upper layer of the underpart of its sheath, and another forward to become continuous with the ocular conjunctiva and the inferior tarsal cartilage. It is united to the inferior cartilage by a short thick process which it gives off in front. In contact with its lower surface is the sheath of the inferior oblique.

Where the suspensory ligament mingles with the capsule of Tenon, the thickness is slightly more than one tenth of an inch. The most important action of the suspensory ligament is, obviously, to support the eye."

Fink[24] has recently emphasized and carried forward the work of Lockwood. He has shown that both inferior rectus and inferior oblique have attachments of their sheaths to the suspensory ligament which vary tremendously in density and number from one specimen to the next. Fink makes the flat statement that ". . . the inferior rectus apparently has no direct attachment to the orbital septum or margin of the orbit"; Lockwood, on the other hand, made no such statement although he strongly implied that this was the case by merely not mentioning any attachment of the inferior rectus to the orbital wall.

The sheath of the inferior oblique extends from its origin on the floor of the orbit along the muscle to a point where its outer layer fuses rather firmly with the inferior surface of the ligament of Lockwood. The muscle itself, accompanied by the inner layer of its sheath, meanwhile penetrates the suspensory ligament and the capsule of Tenon at a point somewhat posterior and lateral to the site of penetration of the inferior rectus muscle. The inferior oblique passes on through the suspensory ligament and the capsule of Tenon to its insertion near the macula.

Near the insertion of the inferior oblique, its sheath spreads out anteriorly to fuse with the sheath of the lateral rectus muscle; posteriorly, its sheath spreads out to fuse with the dura of the optic nerve.[22] The union between the sheaths of the inferior oblique and lateral rectus is sometimes quite firm and effectively binds the two muscles together while at other times it is very loose.[24]

The posterior extension of the sheath of the inferior oblique usually fuses with the dura of the optic nerve and is pierced by the posterior ciliary arteries and nerves which enter the globe temporal to the optic nerve. Fink[22] has emphasized that effective surgery of the inferior oblique includes division of both of the attachments of its sheath to the lateral rectus muscle and to the optic nerve and a good deal of caution is required in separating the latter.

Motais[25] originally described what he considered to be a check ligament for the inferior oblique, but Whitnall[2] denied the existence of any such structure. The recent work of Fink[24] confirms the general findings of Motais, however, and is detailed enough to leave little doubt that such a structure exists.

According to Fink, the check ligament of the inferior oblique muscle leaves the anterior border of that muscle about 8 or 10 mm. from its point of origin and courses obliquely forward, outward, and downward; it leaves the sheath of the inferior oblique at an angle of about 110 degrees.

The check ligament is about 10 to 12 mm. in length and is probably better described as a broad meshwork of fascial fibers rather than as a definite band or ligament, but it serves as an attachment for the sheath of the inferior oblique to the floor of the orbit at a point 4 or 5 mm. behind the orbital margin. Its width varies at different parts of its course so that it presents the shape of two triangles united by their apexes.

Together with the inferior oblique itself, the check ligament forms a kind of musculoaponeurotic loop, the two ends of which are inserted near the orbital margin, one at the outer angle and the other at the inner angle. Strands from the sheath of the inferior rectus, which might be considered as its check ligaments, embrace the midde portion of this loop so that when the inferior rectus contracts, these attachments stretch the loop.[24]

Motais[25] called the ligament of the inferior oblique a ". . . pulley of reflection," suggesting that when the muscle contracted, its check ligament pulled the middle of the belly outward and laterally, thus making its

line of traction on the globe a little less oblique. This would, of course, result in greater elevation and less extortion, particularly in adduction, and would explain even more fully the observed phenomenon of normal overaction of the inferior oblique.[19]

The septum orbitale

The septum orbitale is another portion of the fascia of the orbit which is a connective and elastic tissue membrane extending from the arcus marginale all around the opening of the orbit centrally toward the palpebral fissure. The septum in the upper lid is inserted into the skin of the upper lid, being carried forward by the levator fibers.

Whitnall[2] has pointed out that when the downward extending septum meets the levator fibers, its deeper layers are carried slightly backward to fuse with the levator's aponeurosis, thus shutting off the orbital contents from the interior of the upper lid.

He has also shown that in the upper lid, the septum orbitale is not fixed in a vertical plane but moves and folds with movements of the lids. The septum orbitale coming from the inferior portions of the arcus marginale is inserted into the inferior margin of the tarsal plate of the lower lid.

The palpebral ligaments

The medial and lateral palpebral ligaments are the final portions of the fascia of the orbit to be considered. They arise as extensions of the ends of the tarsal plates in the upper and lower lids and fuse at the inner and outer canthi to run as single ligaments to the medial or lateral wall of the orbit, as the case may be.

Whitnall[2] has shown that the medial palpebral ligament runs anterior to the dome of the lacrimal sac; immediately after it is formed, however, by a confluence of extensions from the medial ends of the tarsal plates, it gives off a smaller posterior division which runs behind the dome of the lacrimal sac to be inserted on the posterior lacrimal crest and it is to this posterior extension that the check ligaments of the medial rectus muscle become attached.

The lateral palpebral ligament is attached to the orbital tubercle of the zygomatic bone. Injuries which result in complete division of the medial palpebral ligament are quite disfiguring cosmetically because of the sunken appearance of the medial canthus which is produced.

Callahan[26] has recently reported the use of fine steel wire passed from the cut end of such a sectioned medial ligament to the medial wall of the orbit and through small holes drilled in the bone there by means of a dental drill; this results in a very satisfactory repair by abolishing the sunken inner canthus.

THE VERTICAL ELEMENT IN THE CAUSATION OF SO-CALLED HORIZONTAL CONCOMITANT STRABISMUS*

Surgical principles for the vertical corrections

Edmund B. Spaeth, M.D.
Philadelphia, Pennsylvania

Strabismus is an abnormality of the visual axes due to several different etiologic conditions. At this time paralytic lateral strabismus is not being considered but all other forms have a definite relationship to this presentation.

It seems, if one is to speak of a lateral concomitant squint with a vertical component present in that squint, that that case is not purely concomitant. If this is true, then also is it true that the most common form of pure lateral concomitant strabismus is the classical alternating type of strabismus wherein the patient has the same degree or angle of squint for near and for distance, both objective and subjective angles being the same, the refractive error being practically equal and negligible in each eye, and this having no relationship to the degree of squint in any convergence-accommodation ratio relationship. In this type of strabismus the patient frequently uses each eye at will, or one eye for near and the other eye for distance, and in these cases there is alternating suppression with alternate functional central scotomas. It is rather interesting to compare this type of squint (in considering vertical relationship) with a classical case of accommodative strabismus, that specific case also having a vertical component.

It is likely that the greatest etiologic factor in the development of strabismus is in the sensory realm. There is no doubt, however, that a large number of cases have, as a most important factor in etiology, a motor defect. It makes little difference whether this is peripheral (orbital) or central—that is, nuclear. See Figure 1. This patient, with a paralysis of the inferior oblique muscle and the superior rectus muscle, both on the left, could hardly have a peripheral incomplete abnormality. When one adds to that the finding of a unilateral ptosis on the right, then also does it seem certain that her condition must have been a bilateral, central, brainstem (probably internuclear) congenital developmental defect.

Figure 2 shows a frank alternating strabismus with no vertical component whatsoever; the right eye fixing, or the left eye fixing; it also illustrates the results following surgery. Even in this, however, with

* From the Graduate School of Medicine, University of Pennsylvania. Presented before the III Pan-American Congress of Ophthalmology, Havana, Cuba, January 8, 1948.

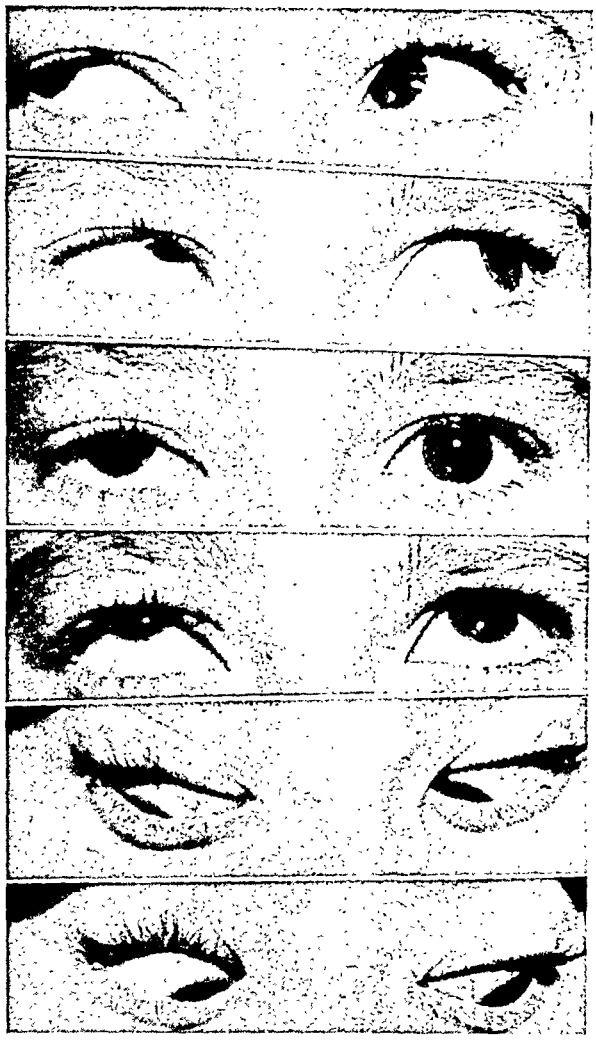

Fig. 1 (Spaeth). Paralysis of the inferior oblique and superior rectus muscles, both on the left. This could hardly have a peripheral incomplete abnormality.

careful study one can see a difference in the palpebral fissures and a bare suggestion of retraction in the right eye; that is, a motor defect. The patient had 6/6 vision in each eye; there were no limitations in ocular motility; he had a negligible equal refractive error of less than plus one (hyperopia), sphere and cylinder combined, bilateral suppression scotomas, and diplopia could not be elicited at any time.

Figure 3 illustrates an almost pure accommodative squint. Vision was 6/12 and 6/6. The refractive error was a plus four, total sphere and cylinder combined, in the right; and a plus two, sphere and cylinder combined, in the left eye. The squint increased at near and disappeared almost wholly under full cycloplegia and with the correcting glasses. There was no doubt that this case had a marked so-called accommodation-convergence relationship, without any lateral oculomotor palsy. The patient showed, however, in right lateral rotations, a definite overaction of the left inferior oblique muscle, the barest amount of overaction of the right inferior oblique muscle, and a slight underaction of both superior oblique muscles. There was no certainty that this child did not have a very moderate elevator palsy of some type. The case was wholly free from strabismus at near, under cycloplegia, and with her full correction.

If a paralysis of a vertical elevator was absent, then this case of practically pure accommodative strabismus must have had, in addition, an accompanying overaction of the inferior oblique muscles. One wonders whether this could be connected in any way with her overconvergence, in this way causing a bilateral inferior oblique spasm. That was simultaneous with the overconvergence and became most manifest when the eye was in a position for the maximum of vertical inferior oblique muscle action; that is, the inferior oblique muscle spasm being at maximum in the left eye with right rotations, and in the right eye with left rotations.

The question of a vertical component as a part of convergent strabismus, in fact of almost any type of lateral strabismus, should give us an inkling as to the causation of strabismus in a certain percentage of cases. This seems especially so when one studies all cases of strabismus, in detail, with the screen test, fixational reflexes, and with prisms in the six cardinal positions. Very few cases of apparently concomitant, nonaccommodative (even of accommodative), monocular lateral squint are found which do not have disturbances in the vertical rotations. The question of cause and effect for each of the two components is at least interesting.

Binocular vision is achieved by the de-

velopment of a conditioned reflex and not because of the presence of an inherent urge that compels the infant or young child to swing into single binocular vision, if this is possible. Fusion as such follows the establishment of this as a conditioned reflex. It (the reflex) is the result of the search and struggle for single binocular vision and the fixation of that, when achieved, and not because of it; that is, fusion or single binocular vision.

Fusion, as a term for an ocular function, is better considered as being quantitative in character, rather than qualitative. The simultaneous use of both eyes, and with this a single cerebral visual concept having certain characteristics (single binocular vision),

Fig. 2 (Spaeth). A frank alternating strabismus with no vertical component whatsoever.

while clumsy as a definition is a qualitative characteristic. The degree of perfection in this function (single binocular vision) as a conditioned reflex is to be measured in terms of fusion.

There are two factors which permit the formation of a perfectly conditioned reflex wherein the child obtains a single cerebral visual concept. They are the synchronous use

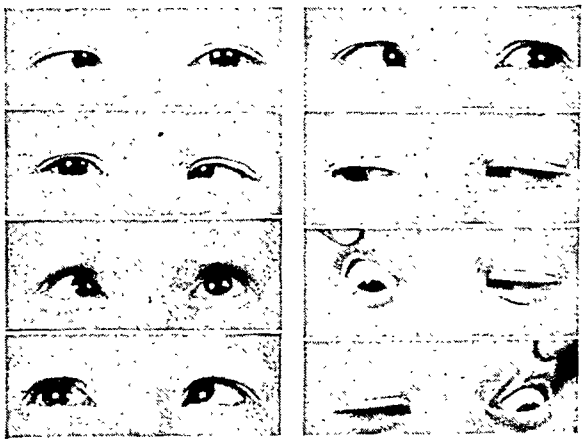

Fig. 3 (Spaeth). An almost pure accommodative squint.

of the two cerebral hemispheres and, at the same time, the simultaneous use of the two eyes. This, of necessity, implies the presence of two attributes or essentials; one is in the motor sphere, the other is in the sensory realm. If there are neither sensory nor motor obstacles present, the patient should progress normally to single binocular vision and this should be well established by the 4th or 5th year of life.

Motor obstacles may include such conditions as temporary to permanent anatomic disturbances from birth injuries, defects affecting the orbits and the globes, faulty insertion of muscles, fibrosis of a muscle (as one sees in the Duane syndrome) which is probably an imperfect mesodermal development of an ocular muscle, aplasia of an oculomotor nucleus, and contracture of the antagonist of a muscle imperfectly exercised.

Sensory obstacles must include not only the many possible peripheral sensory retinal situations, but also possible conflicts between the occipital lobe involuntary accommodational reflex, the frontal lobe voluntary accommodation-convergence reflex, and the internuclear brain stem accommodation-convergence reflex—normally of greatest importance in conditioning binocular single vision. An abnormal convergence innervation consequent to disturbances in these three is probably the greatest of the faults in the sensory realm. Such defects are either an

excess in convergence or a deficiency in convergence. A discussion of these is not relevant at this time, except to take recognition of the role they play. Also, one must not

Fig. 4 (Spaeth). A case of alternating divergent strabismus of a moderate degree of severity, with marked inferior oblique muscle overaction.

overlook the fact that the convergence excess of accommodative squint, with full correction (refraction), frequently shows a convergence insufficiency.

As the infant strives to develop single binocular vision, as a result of his awareness to diplopia, he may fail in meeting and overcoming sensory or motor obstacles and so he also fails to obtain normal single binocular vision. Instead, strabismus of some type develops through the conflict between a normal sensory situation and a faulty motor balance; or a faulty sensory state and a normal motor condition; or the not uncommon condition wherein both are faulty although to dissimilar degrees.

Faulty vertical function is an outstanding motor obstacle. It is not necessarily limited to convergent strabismus but it is for some reason somewhat less common in divergent strabismus. Divergent strabismus, except the monocular type, is not an attribute of very early childhood, and the incidence of divergent squint is rare, as compared with convergent squint. One might suspect that diverging visual axes discourages an overaction of the oblique muscles. This, however, seems to reverse the order of cause and effect. Disturbances in the vertical element nevertheless do appear frequently.

Figure 4 is a case of alternating divergent strabismus of a moderate degree of severity. The child in the upper photograph is fixing with the left eye. (See position of the pupillary reflexes.) Movements up and to the right and up and to the left show a marked overaction of the contralateral inferior oblique muscle. There were no disturbances

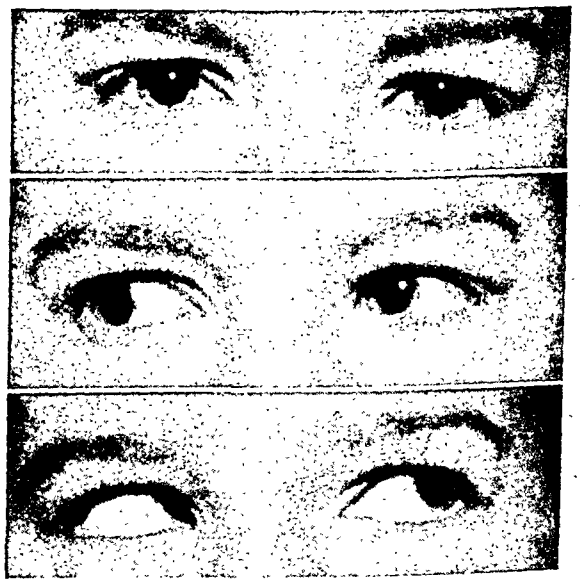

Fig. 5 (Spaeth). A unilateral case in which the inferior oblique muscle is rotating normally in amplitude but its conjugate yoke muscle is rotating to a limited degree.

in visual acuity. This is the type of case which will certainly continue to advance into more and more pathologic divergence.

In this paper, the term "overaction" is being used rather loosely. It is not always applied upon pure physiologic principles, but only in terms of an increase in the amplitude of excursions of the eyeball as the re-

sult of the action of a certain muscle. In addition, inhibitional palsy is not being considered for it is not relevant here.*

The vertical component is not necessarily the result of the overaction of an inferior

Fig. 6 (Spaeth). A bilateral case of the inferior oblique muscle rotating normally in amplitude but its conjugate yoke muscle rotating to a limited degree.

oblique muscle. There is no doubt that in many instances one can state definitely that there is limitation in the field of action of a superior rectus muscle and, therefore, the contralateral inferior oblique muscle is overacting secondarily. This can be explained upon the basis of two possibilities.

The first of the two is that the inferior oblique muscle is rotating normally in amplitude but its conjugative yoke muscle is rotating to a limited degree. The action of the inferior oblique muscle is relatively greater now only because of its normal nerve and muscle anatomy. This would be

Fig. 7 (Spaeth). A true overaction is caused when a greater than normal innervational effort is put forth in the attempt to obtain a maximum amplitude of movement in a paretic muscle, causing overstimulation of the conjugate yoke muscle.

Fig. 8 (Spaeth). A relative underaction of the right inferior rectus muscle and an overaction of the left superior oblique muscle. A congenital ptosis with a possible involvement of the superior rectus muscle is also present.

purely a peripheral situation and would exclude any effect from a desire for binocular single vision. Figure 5 seems to be such a case, unilaterally, and Figure 6 bilaterally. Neither of these patients had any lateral strabismus when under the cycloplegia, as photographed.

The second likely and certainly more frequent situation, as seen, for instance, with a paretic superior rectus muscle, occurs as follows. A greater than normal innervational effort is put forth by the patient in his attempt (or wish) to obtain a maximum amplitude of movement in this paretic

* This applies, in the vertical disturbances, in cases in which the patient is using, for fixation, the eye with an involved vertically acting muscle. The inhibitional involvement will then appear in the opposite eye. In such instances, considering the basic purposes of this presentation, both horizontal deviation and vertical inhibition might be seen in the same eye.

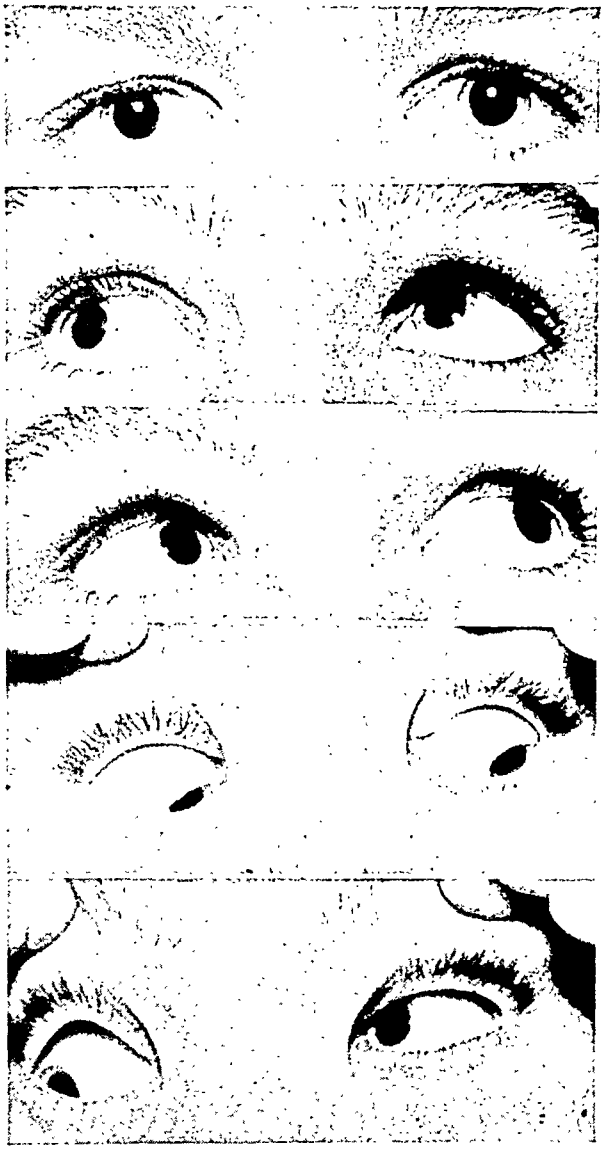

Fig. 9 (Spaeth). An accommodative strabismus, the horizontal component of which was eliminated by cycloplegia.

muscle, and perhaps to hold binocularity (distaste for diplopia) and because of that, the conjugate yoke muscle, cerebrally controlled and from a nuclear source, has a true overstimulation, and thus a true overaction. Figure 7 illustrates this condition and shows especially the overaction in the right eye.

Similarly, one should see this same relationship between an overacting superior oblique muscle in one eye and an underacting inferior rectus muscle in the contralateral eye. In these instances true limitation of the ocular rotations are picked up more rapidly.

Figure 8 shows, in downward movements to the right, a relative underaction of the right inferior rectus muscle and an overaction of the left superior oblique muscle. This was not present in left lateral rotations in which the depressors of both eyes were equal and balanced in the extent of their motility. The comparison of the maximum possible action of each inferior rectus, separately, is the important diagnostic criterion as to laterality in this case.

Figure 8 illustrates another complexity. This complication is that of a congenital ptosis of the left eye with a possible involvement of the left superior rectus muscle. Repeated studies in this child did suggest the possibility of a primary or essential overaction of the left superior oblique muscle in the presence of a normal right inferior rectus muscle. This was based upon a comparison in degrees of the rotations of the two inferior rectus muscles in the two eyes. The patient thus has a possible limitation in the action of the left superior rectus muscle, the left levator muscle, possibly the inferior rectus muscle in the right eye, and an overaction of the superior oblique muscle in the left eye. These muscle details are emphasized to illustrate the complexities in the diagnosis of the primary and the secondary deviations, as well as the effect of unilateral vertical muscle antagonists.

Another possibility which must be seriously considered is not a true or even relative overaction of a conjugate yoke muscle (primary paretic pathologic process in one eye; overaction in the other eye) but the relative overaction of the direct monocular muscle antagonist to a paretic muscle. In considering any one of the vertically acting muscles as, for instance, the superior oblique muscle, the question (fig. 9) is not one of a probable nuclear aplasia of the fourth-nerve nucleus or of any type of possible fourth-nerve involvement; it is specifically the consideration of a frankly underacting superior oblique in one eye with a strongly overacting inferior oblique in that same eye, the eyeballs being rotated for this demon-

stration into the position of greatest vertical action for the oblique muscles under consideration.

The child in Figure 9 has an accommodative strabismus (O.D.), the horizontal component of which was eliminated by cycloplegia (as can be seen in the upper of these photographs) wherein downward rotations to the right showed the paresis of the left superior oblique muscle, while upward rotations to the right brought out the overaction of the inferior oblique muscle of the same eye, the result of a direct monocular antagonist.

Another matter is relevant at this point. It is the all too frequently heard statement of a vertically acting "weak muscle." This adjective can be applicable only in cases of faulty muscle-tendon insertions, or of mesodermal maldevelopment. All other anatomic and hence functioning causes are more likely defects within (and in) innervation; hence, truely paretic in nature.

Figure 10 shows a similar but even more convincing case, although it is not a pure lateral concomitant strabismus. The patient had an almost complete paralysis of the superior division of the left third nerve. Marked secondary overaction of the right inferior oblique muscle is seen, mild underaction is present in the left inferior oblique muscle (perhaps the result of a subtotal paralysis of the left third nerve), and with it an overaction in the two direct monocular antagonists—the inferior rectus on the left, the result of the superior rectus paralysis; and the superior oblique on the left, the result of the underaction of the left inferior oblique muscle.

Figure 11 is a case in which both levators of the left eye were involved; that is, an evident impairment of the left inferior oblique muscle and a lesser degree of impairment of the left superior rectus muscle, suggested as such because of the overaction of the right inferior oblique muscle. It is interesting that in this patient there is no overaction in either of the monocular

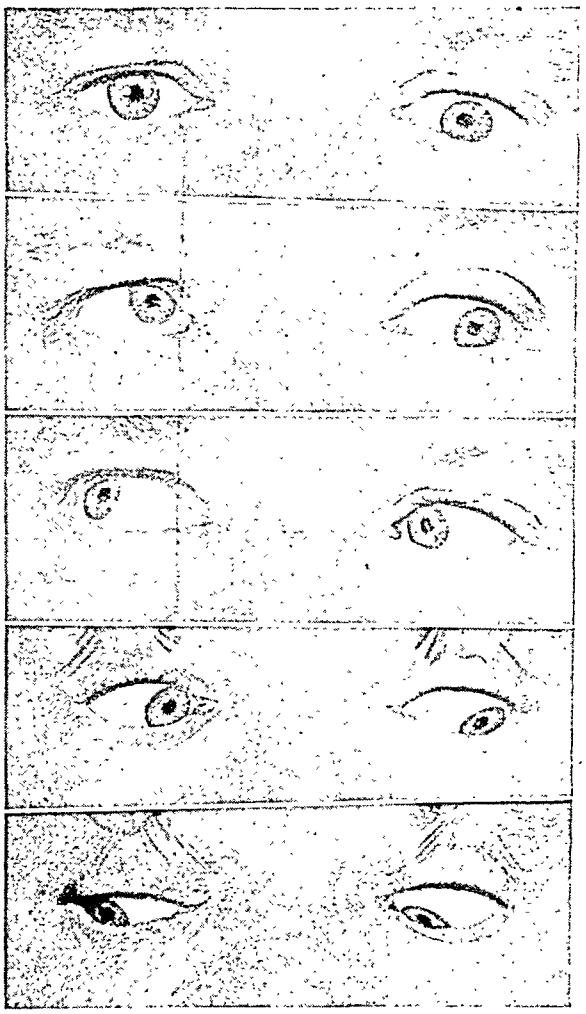

Fig. 10 (Spaeth). An almost complete paralysis of the superior division of the left third nerve.

direct antagonist muscles. This case illustrates well the fallacy of orthoptics in this type of case, except for those exercises to combat the amblyopia. This patient had had many months of exercises in another city, and the mother stated "without changing the cross-eye in any way." One wonders whether the vertical element was considered at the time the ophthalmologist outlined the orthoptic treatment.

Figure 12 presents a mild monocular convergent strabismus in the left eye, with a marked amblyopia. There is a marked increase in the convergent strabismus present when the patient is compelled to use the paretic inferior oblique muscle on the left. There is, however, no gross overaction of

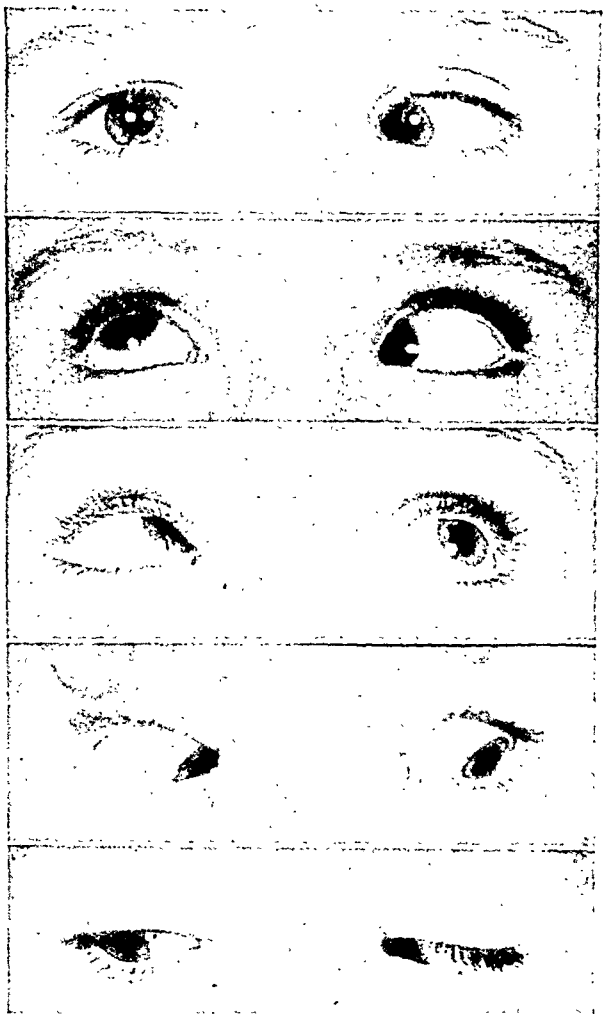

Fig. 11 (Spaeth). Impairment of both elevators of the left eye.

his conjugate muscle; in this instance, the superior rectus muscle on the right. Also, in his case there is little, if any, overaction of the monocular antagonist, the superior oblique muscle of the left eye. His vertical rotations to the opposite left side were normal and balanced. Here, certainly, one can see a *spasm* of an internal rectus muscle consequent to a vertical muscle disturbance.

Figure 13 is a case of bilateral limitation of equal degree in the field of the inferior oblique muscles.

This patient, aged four years, had a transient convergent strabismus, present when fatigued but with some amblyopia already established, showing the sensory suppression put forth for physiologic ocular comfort. There was neither contralateral synergist nor homolateral antagonist muscle overaction. There may have been some underaction of the left superior oblique muscle. The condition illustrated is essentially one of bilateral hypophoria. The patient is suppressing in one eye only; he has good stereopsis; and the inferior oblique muscles are both faulty. Torticollis was present and was constantly toward the right.

The problem of differentiating an overacting inferior rectus muscle with a contralateral relatively (comparative) underacting superior oblique muscle from an underacting superior rectus muscle with a contralateral relatively overacting (again comparative) inferior oblique muscle appears occasionally for solution in any certain case. Both of these conditions, frequently, have a marked degree of lateral strabismus.

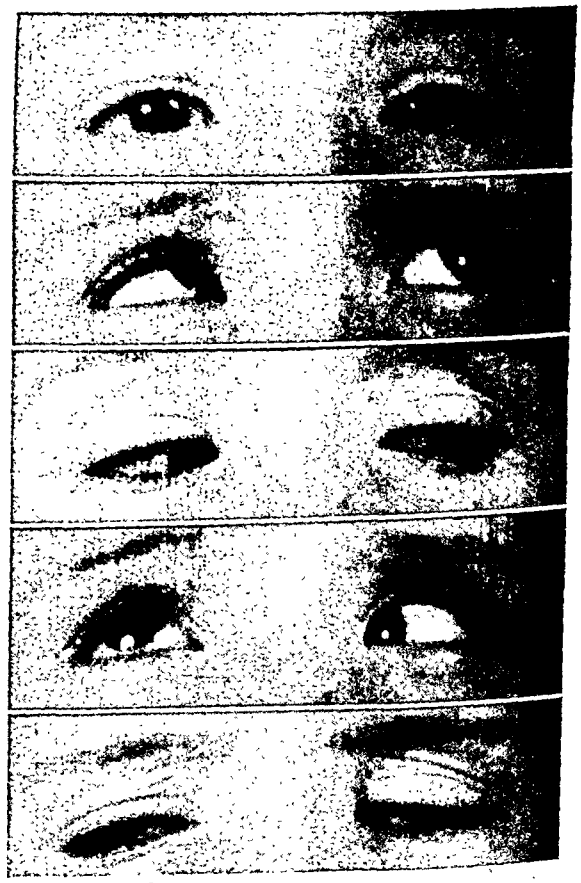

Fig. 12 (Spaeth). A mild monocular convergent strabismus with a marked amblyopia. There is a marked increase in the convergent strabismus present when the patient is compelled to use the paretic inferior oblique muscle.

Figure 14 illustrates this. The child has a monocular convergent strabismus on the left with vertical movements to the right practically equal and balanced. Vertical movements, however, downward and to the left show an overaction in the field of the left inferior rectus muscle with normal and balanced rotations in the fields of the left superior rectus muscle and the right inferior oblique muscle. This permits one to feel that the right superior oblique muscle is paretic rather than the left superior rectus muscle being in essential underaction. The presence of torticollis in such a case would be of great assistance in confirming a diagnosis as to which muscle is involved. Also,

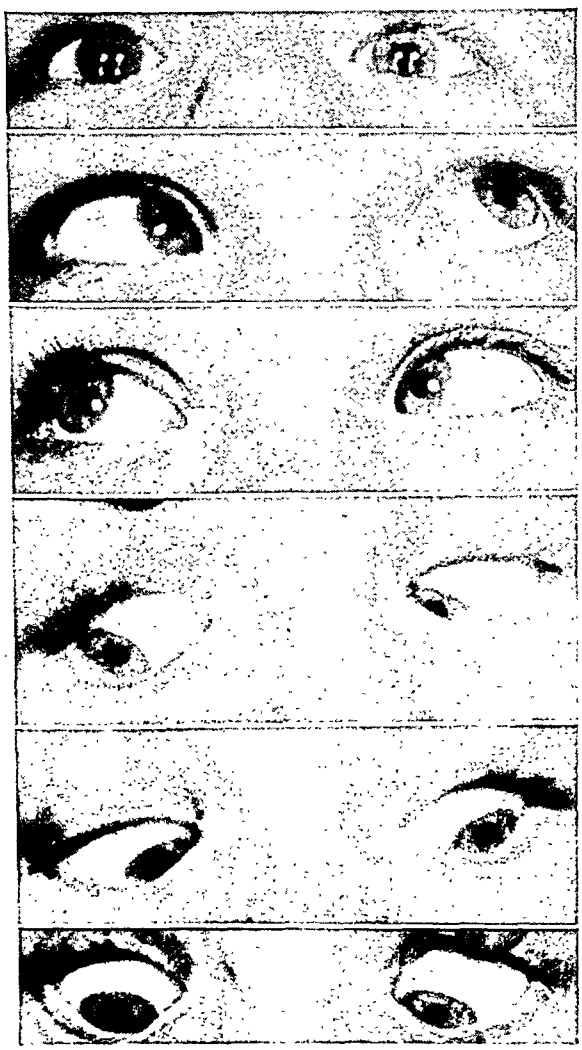

Fig. 13 (Spaeth). Bilateral limitation of equal degree in the field of the inferior oblique muscles.

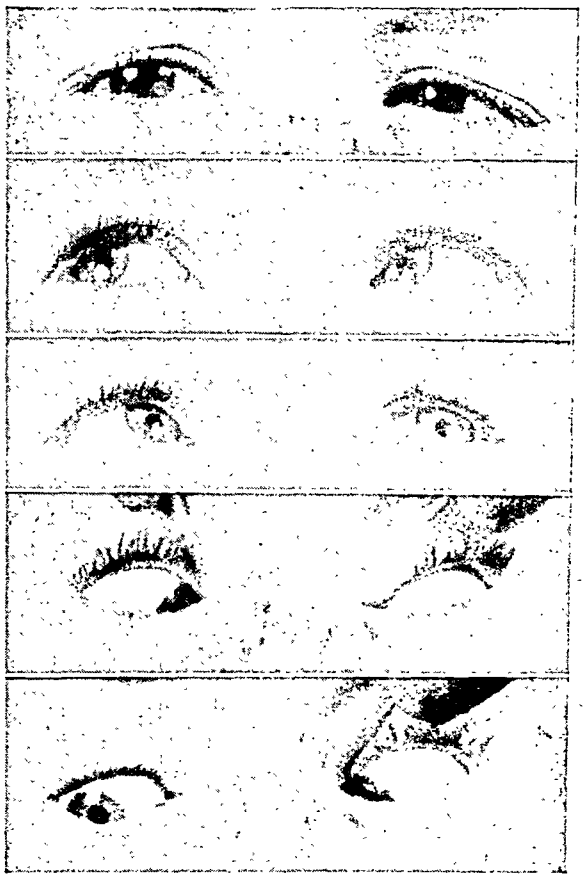

Fig. 14 (Spaeth). A monocular convergent strabismus on the left with vertical movements to the right practically equal and balanced.

if suppression and amblyopia are not present, a compensatory movement of the eye can be seen (as first noted by Bielschowsky) when the observer straightens that torticollis manually. The problem, of course, is the differential diagnosis between a paresis of a superior rectus muscle and of a superior oblique muscle. These cases (fig. 14) do not have diplopia because of suppression and, hence, amblyopia results. If that were not so, differential diagnosis would be a simpler problem. An acquired vertical muscle paralysis, by contrast, without suppression and without concomitant strabismus offers relatively few difficulties in differential diagnosis.

Figure 15 is a somewhat similar problem except here one must differentiate between a paresis of the right superior rectus muscle, the right inferior oblique muscle, and the

Fig. 15 (Spaeth). In this case it was necessary to differentiate between a paresis of the right superior rectus muscle, the right inferior oblique muscle, and the left inferior rectus muscle.

left inferior rectus muscle. The vertical deviation in the left eye could be secondary to a right inferior oblique muscle palsy. The frank limitation of movement, however, in the field of the left inferior rectus muscle with possibility of a direct antagonistic overaction of the left superior rectus muscle makes the diagnosis rather conclusive.

The differentiation of a primary and a secondary action is rather important, because surgery when necessary for a vertical

Fig. 16 (Spaeth). A frank hyperactivity (bilateral) in the contralateral rotations of the inferior oblique muscles without any lateral deviation present at any time.

component is at times successful only when applied to the conjugate overacting muscle (secondary deviation) and not to the primary underacting paretic muscle; at other times the reverse is true.

Vagaries and inconsistencies in the vertically acting muscles are not too uncommon. Figure 16 shows frank, bilateral inferior oblique muscle hyperactivity in the contralateral rotations without any lateral deviation present at any time. The refractive error was equal in both eyes. The patient may have had bilateral minimal paralyses of the two superior recti but, if so, these were equal in amount, for the measurement of the maximum contralateral hyperphoria was exactly the same in prism diopters and diplopia could not be elicited at any time. Even more significant was this, the vertical muscle situation did not result in any lateral strabismus nor in the development of subjective ocular symptoms.

Another instance follows. A patient was seen very recently with an ordinary, apparently congenital, sixth-nerve palsy on the left and without limitation of upward gaze in the midline (fig. 17). When left lateral rotations were demanded, not upward but on the horizontal level, the overaction of the internal rectus muscle on the right, consequent to the paralysis of the external rectus muscle on the left, was accompanied by an overaction of the right inferior oblique muscle (bottom view, fig. 17).

This overaction of the right inferior oblique muscle increased with attempted upward gaze to the left, even though the paralysis of the left external rectus muscle prevented the left eye from rotating into the field of the greatest vertical action for the conjugate yoke muscle of the right inferior oblique; that is, the left superior rectus muscle. One may say, therefore, that in this case a true spasm was present in the inferior oblique muscle. Normally this muscle should not be affected, in this overaction, by left lateral rotations on the horizontal level. It

seems as if the overaction of the inferior oblique muscle must be connected with the simultaneous overaction of the right internal rectus muscle. This has been suggested before in considering overconvergence.

It must be remembered, in these cases, that the patient should develop the horizontal strabismus in the eye with the greater refractive error, accompanied by sensory inhibition and amblyopia, but the vertical element connected with the case, and responsible, in part, for the lateral squint may be in either of the two eyes. This disturbance in the vertical may be found, although not as frequently, in the nonstrabismic eye as in that with the manifest squint.

Clinical experience seems to suggest that when the involved vertically acting muscle is on the eye which has the higher refractive error, then, also, one will find that the vertical component present in that case will be greater than the lateral component.

Figure 18 is a case with accidental alternating strabismus, the greater deviation being in the left eye. The vision in the right eye was 6/7.5, and in the left, 6/60, with correction. The refractive error, plus sphere and cylinder combined, was greater in the left eye. The horizontal deviation was largely present in the left eye. Nevertheless, the vertical muscle pareses were in the right superior rectus muscle and the right inferior oblique muscles. The greatest overaction present, and as a secondary deviation, was in the left inferior oblique muscle.

Figure 19 is one of a child with a paresis of the right inferior oblique muscle. The lateral deviation is seen in the right eye and it is not marked. The vertical deviation is the greater of the two. The right eye has developed amblyopia in this child and the patient consistently fixes with the left eye. The light reflexes, corneal, of the three upper photographs of Figure 19 are rather conclusive. In this case of lateral concomitant

Fig. 17 (Spaeth). A sixth-nerve palsy with normal upward gaze in the midline.

strabismus the vertical component is appreciably greater than is the lateral. This is a logical sequence of events.

One must be sure, however, not to confuse the fixing eye in such instances with a possible secondary manifest deviation, such a

Fig. 18 (Spaeth). An accidental alternating strabismus.

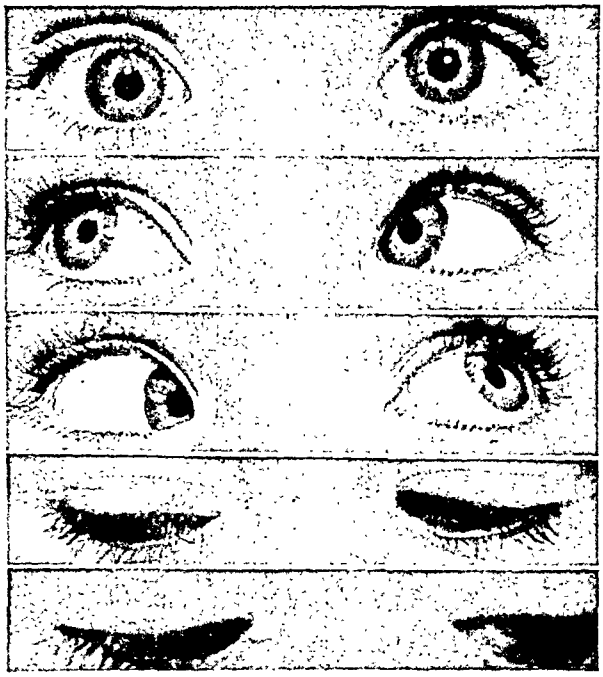

Fig. 19 (Spaeth). A paresis of the right inferior oblique muscle.

deviation being the result of fixation with the eye having the vertically paretic muscle. Figure 20 is another interesting deviation from that which one might expect. The child had a paresis of the superior rectus muscle on the right and some levator involvement as well, with a divergent strabismus on the right. There was no appreciable left inferior oblique muscle overaction, neither was there any right-sided superior oblique overaction in downward gaze. There was, however, in the rotations directly downward, a marked overaction of the right inferior rectus muscle. In this case if a levator had not been simultaneously involved on the right, one would be suspicious of an inferior rectus fibrosis limiting the upward excursions of the right eyeball in a manner similar to a lateral retraction syndrome. Surgical examination of the inferior rectus muscle revealed a perfectly normal muscle.

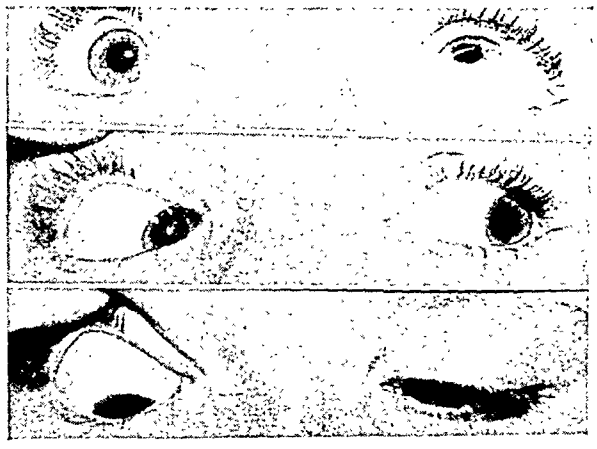

Fig. 20 (Spaeth). A paresis of the superior rectus muscle and some levator involvement, with a divergent strabismus.

Fig. 21 (Spaeth). A monocular convergent strabismus with torticollis toward the left.

These cases, if carefully observed, will frequently show torticollis to varying degrees—sometimes moderate in amount, at other times quite marked. The presence of torticollis suggests a fair prognosis for the reëstablishment of postoperative single binocular vision because it is a defense mechanism for escaping diplopia.

Figure 21 is a monocular convergent squint with a rather marked torticollis toward the left, with underaction of the right superior oblique muscle, and with normal vertical movements to the right. It was this head tipping which occasioned the patient's first visit to the oculist. (He was referred by an orthopedist.)

The various essential factors connected with and related to these cases can be uncovered only by accurate prism measurements. These should be done with screening and with prisms in the six cardinal positions, before and after cycloplegia, checked for certainty, and carefully noted upon a spider graph (that formerly suggested by Duane or the more recent one of White's are equally satisfactory). Amblyopia and suppression must be broken down so that measurements are obtained with an approximation to macular fixation, for extramacular fixation tends to exaggerate conjugate yoke muscle secondary deviations, as it changes the prism measurements of the objective and subjective angles of squint.

Recapitulation

The entire problem of a vertical component in so-called concomitant strabismus must be considered from the following standpoints.

1. *Congenital disturbances.* The likelihood that congenital disturbances in the levators, or the depressors, frequently play a profound role in the development of convergent and divergent lateral strabismus of all types, probably excepting true or essential alternating strabismus. It seems that the absence of this is an attribute of a correct diagnosis of that type of squint.

2. *The uncovering of a vertical element* in a case under consideration and the diagnosis of the primary and the secondary deviations are basic. Not only is it necessary to make a diagnosis of the type of muscle condition present but also to identify the muscle or the muscles involved. It is well to remember that when a left superior oblique muscle palsy is confused with a possible right superior rectus muscle palsy, or a left inferior oblique muscle palsy with a possible right inferior rectus muscle palsy, that the torticollis is always toward the side opposite from the eye involved. Supression of vision and amblyopia are the patient's means of fighting the cause of the torticollis, hence torticollis is not as constant a sign as it might be.

3. *Accommodative strabismus* can be complicated by an inferior oblique muscle hyperaction without demonstrable paresis of the contralateral synergist.

4. *Oblique muscle overaction* is not unusual, inferior or superior, and is due either to a paresis of the contralateral synergist yoke muscle, to a paresis of the homolateral direct antagonist, or to some mechanical defect in the orbit itself—probably connected with fibrotic bands in and to the check ligaments.

5. *A similar overaction* occurs in the inferior and superior rectus muscles as in the oblique muscles, consequent to similar factors. These cases are perhaps less common.

6. *The greatest vertical deviation* need not be present in the amblyopic eye. The horizontal squint, however, is present in that eye and this is the primary lateral deviation.

7. *Lateral concomitant deviation.* It is not always possible to state that the lateral concomitant deviation is due: (a) to the paresis of a vertically acting muscle; or (b) to the secondary deviation of a synergist to a paretic muscle; or (c) to the overaction of the direct antagonist to a paretic muscle. All three may be of significance together or at different times. Because of that the next paragraphs are perhaps the most significant in surgical therapy.

8. *The surgical therapy* for these situations is important. The results of clinical experience (and as such it should be seriously considered) has resulted in the following conclusions.

a. It is wasted time and an unnecessary expenditure of money to attempt the cor-

rection of these cases by orthoptics for they are certainly pure surgical conditions. The surgical correction should be done, if possible, before the age of four years.

b. If the vertical deviation is greater in amount than the lateral (horizontal) deviation it should be handled surgically first.

c. If the lateral deviation is the greater in degree, then that should be operated as the initial procedure. Lateral deviations tend to diminish in degree following corrective surgery to a vertical component, but vertical deviations may decrease or increase in any amount following the surgery to the lateral muscles, when that should be the primary operative procedure.

d. As the vertical component approaches the lateral component in degree or amount of deviation, then also will it be necessary to use surgery for the vertical element, either as a primary, a secondary, a simultaneous, or a subsequent operative procedure.

e. Satisfactory single binocular vision with good working fusion can never be obtained as long as a vertical component is present to an appreciable degree.

f. Minimal residual amounts of a vertical deviation lend themselves well to surgery. Surgery is only successful when applied to the proper deviation, either the primary or the secondary deviation, as indicated in any given case. Three surgical procedures are available, and at times necessary. Either the paretic muscle must be augmented in its effect, or the overacting conjugate yoke muscle limited in its overaction, or the direct antagonist to the paretic muscle in the same eye limited in its relative overaction. The following are good working rules.

Habitual fixation with the paretic eye needs surgery to the conjugate yoke muscle.

Marked torsional defects in the image, as manifested by torticollis, extensive paralysis of a muscle, and secondary overaction of the direct antagonist need surgery to the paretic muscle. This is also so when the eye without the vertical palsy is the fixing eye.

Surgery to the conjugate yoke muscle is indicated in spasm of the conjugate yoke muscle, in the lesser degrees of paralysis, and as an additional procedure to augment the effect of surgery to the paretic muscle whenever that becomes necessary because of residuals.

Surgery to the direct antagonist of a paretic muscle is indicated when spasm is present in that muscle, and as an adjunct procedure with an after surgery to the paretic muscle.

An extensive recession of a superior rectus muscle is seldom if ever indicated, and a tenotomy of that muscle is never permissible.

9. In general, *the sequence of surgical procedures for the vertical muscles* seems to give best results when applied as follows: First, (a) a recession of the overacting synergist, or (b) a resection or advancement of the paretic muscle. Second, a reversal of the sequence of a, and of b. Third, recession of an overacting direct antagonist. This is especially significant in considering the obliques. For example, the recession of an inferior oblique muscle, when overacting, will give a rather poor postoperative result, if, in the case under treatment, the proper procedure should have been the resection of the superior oblique muscle, directly antagonistic to the inferior oblique muscle being discussed. It is important that one select the proper oblique muscle for surgery in any case under consideration.

Conclusions

This presentation with the cases shown has but one purpose—to emphasize a relationship which exists between so-called concomitant strabismus and disturbances in the action of the vertically functioning extraocular muscles. This suggests a factor in the etiology of squint and, by a reversal in the sequence of events, a means for the better correction of the condition. The cosmetic appearance is not the best result obtainable in a case. Single binocular vision, or as close an approach to this as is possible, is the end result desired.

1930 Chestnut Street (3).

HISTOLOGY OF THE RETINA IN A CASE OF TAY-SACHS'S DISEASE*

JOHN A. MACMILLAN, M.D.
Montreal, Quebec

Comparatively few eyes have been examined histologically in cases of Tay-Sachs's disease, or the infantile type of amaurotic family idiocy. Werncke[1] states that not over 15 were examined up to 1939. Since then, Hagedoorn[2] and Hassin[3] have each reported the retinal findings in one case of the disease. To these I should like to add another.

Although the clinical features of the disease are well known there is still uncertainty regarding the histologic changes. Coats,[4] in particular, found only changes in the ganglion-cell layer of the retina and stated that the histologic changes found in the other layers of the infantile type were of a postmortem nature. While the delay in fixing the globe after death was in some of the reported cases so great that postmortem changes influenced the findings to a degree that conclusions could not be drawn, in others, especially in Hancock's and Coats's[5] case, where the eyes were examined immediately after death, and in Verhoeff's[6] case, where the eyes were removed 15 minutes after death, postmortem changes could not have occurred.

In the case here reported, five hours elapsed before the eyes were removed and placed in fixing fluid but the body was kept in refrigeration from immediately after death. Further, the changes were so definite that we feel they were certainly a part of the pathologic condition present and therefore add more evidence to prove that the changes are not entirely limited to the ganglion-cell and fiber layer but also that there are changes in the inner nuclear layer of the retina.

It is for this reason, and the fact that these changes lend themselves so well to reproduction, that we thought it of value to report our findings. Moreover, confusion has arisen from the use of the term "ganglion cell," which in this paper refers only to the ganglion cell of the ganglion-cell layer. While the bipolar cells of the internal nuclear layer are ganglion cells they are not usually referred to as such.

Hancock and Coats[5] state that the changes in amaurotic family idiocy are absolutely confined to the ganglion cells and their corresponding nerve fibers, yet later on they say that the ganglion cells which normally occur in the inner nuclear layer are also degenerate. This is ambiguous, but it would appear that they meant by this the Dogiel ganglion cell, or those found normally at times in the inner layer of the internal nuclear layer. The changes in the internal nuclear layer (fig. 1B) appear through its whole depth and therefore are not limited to the Dogiel cells.

The name "Tay-Sachs" is derived from Warren Tay,[7] who, in 1881, published a report of a case of symmetrical changes in the region of the yellow spot in each eye of an infant, and from Bernard Sachs,[8] who, in 1887, gave a clinical pathologic account of a similar case under the heading of "Arrested Cerebral Development." The familial characteristics of the disease were established in 1896, when Sachs[9] reported on a sister of his original patient and suggested the name "amaurotic family idiocy." Tay,[10] however, in 1884, had also reported on a third instance in the same family of symmetrical changes in the yellow spot of each eye in an infant.

The disease is defined by Duke-Elder[11] as a familial disease of early life due to

* From the Department of Ophthalmology, Royal Victoria Hospital. Presented before the III Pan-American Congress of Ophthalmology, Havana, Cuba, January, 1948.

primary lipoid degeneration of the ganglion cells of the entire central nervous system, in which the ganglion cells of the retina participate, characterized by unique bilateral fundus appearances and invariably terminating in blindness, paralysis, idiocy, and death.

These are several forms of disease due to widespread lipoid degeneration—Tay-Sachs's disease of the infantile type of amaurotic family idiocy; a late infantile type described by Bielschowsky;[12] the juvenile type also known as Batten-Mayou disease in England, Spielmeyer-Vogt, or Spielmeyer-Stock, disease in Germany; while, in America, Oatman called it familial maculocerebral degeneration.

Other diseases due to lipoid degeneration are Gauthier's disease and Neimman-Pick's disease. The last named may involve the retina as well as practically all the structures throughout the body. In an effort to simplify the various lipoid diseases in which retinal changes may be found, I have constructed Table 1.

TABLE 1

LIPOID DEGENERATION OF THE GANGLION CELLS OF THE RETINA FOUND IN AMAUROTIC FAMILY IDIOCY*

Infantile Type	Late Infantile Type	Juvenile Type	Neimman-Pick Disease
Tay-Sachs About 6 months	Bielschowsky 3–5 years	Batten-Mayou Spielmeyer-Vogt Spielmeyer-Stock Oatman Familial maculocerebral degeneration	Or Lipoid splenohepatomegaly Or Lipoid histiocytosis
Cherry red spot Jewish Female 3-1	Pigment change Nonracial	Second dentition Pigment change Nonracial	

* Also congenital type (Norman and Wood, 1941); and adult type (Kufs, 1929).

CASE REPORT

The case here described is that of a Jewish boy, who died at the age of 17 months, with all the typical signs and symptoms of Tay-Sachs's disease, including the gray area in the posterior pole and a cherry-red spot in the macula of each eye. The eyes were removed five hours after death, hardened in formalin, embedded in celloidin, and sectioned. The following stains were employed: Hematoxylin-eosin, Van Gieson, Bielschowsky, silver carbonate for oligodendroglia and microglia, gold chloride sublimate, phosphotungstic acid, hematoxylin, Nissl, Loyez, Bodian, and osmic acid.

The microscopic findings show a great reduction in the number of ganglion cells in the ganglion-cell layer of the retina (fig. 1). Most of those remaining, especially in the posterior pole, are greatly swollen and the cell bodies show many small vacuoles surrounded by slightly granular cytoplasm (fig. 2).

The cells have lost their multipolar form due to the swelling and are round in shape with the periphery of the cell clearly demarcated. In some the cell bodies cannot be made out and only nuclei can be seen but it could not be determined whether these are nuclei of the nerve cells or of neuroglia.

The nuclei of the swollen ganglion cells occupy an eccentric position in the cytoplasm and stain so densely that nucleoli are not visible. These changes are most marked in the posterior pole of the retina and, as one approaches the ora serrata, the ganglion cells are reduced in number in comparison with the normal and their cytoplasmic outline tends to be stellate rather than globular. The nuclei are not as pyknotic as those in the

posterior pole but Nissl bodies cannot be identified in the cytoplasm.

A finely granular reticulum can be made out about small vacuoles in the cytoplasm as in the nerve cells of the macular region. The nerve-fiber layer is markedly reduced in thickness but, nevertheless, a few nerve fibers are shown by the Bodian stain. There vacuolated. The vacuoles are surrounded by delicate reticular network as in the nerve cells of the ganglion cell layer.

These swollen cells are found in different levels of the internal nuclear layer (fig. 1); that is, in the inner layer where the amacrine cells, and the occasional Dogiel cells, are normally located. They are also found in the

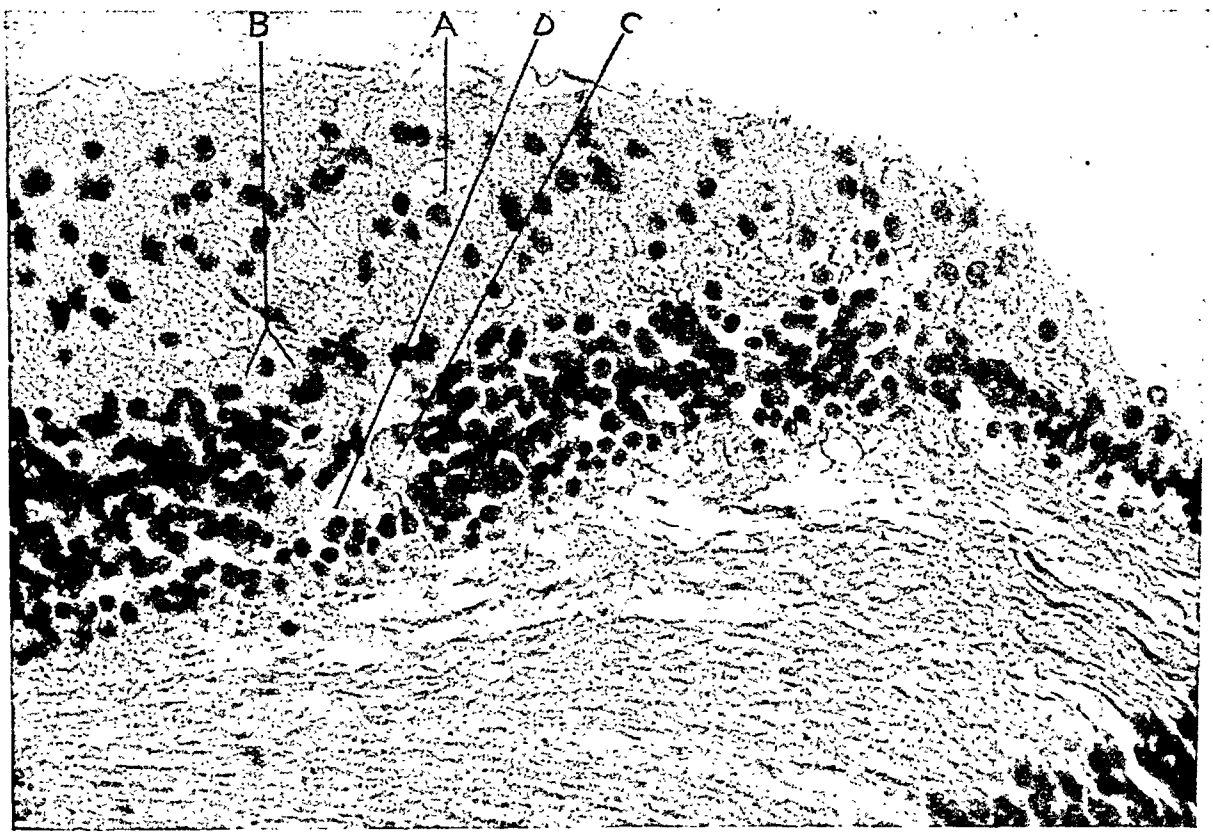

Fig. 1 (MacMillan). MARGIN OF MACULA showing inner layers of the retina. (A) Swollen ganglion cell. (B) Swollen cells in inner part of internal nuclear layer. (C) Swollen cell in middle part of internal nuclear layer. (D) Swollen cell in external part of internal nuclear layer.

is an increase in the number of nuclei in this layer which are undoubtedly glial.

There is nothing abnormal in the internal plexiform layer of the retina. The internal nuclear layer appears of about normal thickness and the cells are so packed together that only nuclear details can be made out. There are in places, however, swollen cells which resemble the swollen ganglion cell above described (fig. 3). These cells also have eccentric nuclei and their cytoplasm is middle portion which is occupied by the bipolar cell and again in the external part of this layer, the normal position of the horizontal cells.

While the bipolar cells are true ganglion cells, the term ganglion cells here is used only for those cells which are in the ganglion-cell layer.

As one approaches the periphery of the retina, the globular cells cannot be identified in this layer. The other layers of the retina;

that is, the pigment epithelium, rods, cones with their nuclei, and the external plexiform layer, are quite normal.

The nuclei in the optic nervehead are greatly increased in number and in sections the nervehead is raised above the retinal level. Nevertheless, the nerve bundles are small in diameter. In the optic nerve the nerve bundles are small, the number of nuclei in the septa is increased, the septa are thickened, and there are clear spaces between the nerve bundles.

Fig. 2 (MacMillan). Higher magnification of (A) in Figure 1.

Comments

The changes in the ganglion cells of the ganglion cell layer and of the nerve cells of the internal nuclear layer are similar, although they are fewer in the internal nuclear layer and they are found only in the posterior pole of the eye. The question can be raised as to whether they are nerve cells. Their location in these two areas is presumptive evidence in a patient with amaurotic family idiocy. They cannot be cells of the reticuloendothelial system or microglia as morphologically they differ greatly. The vacuoles are numerous and small with wide bands of delicately granular cytoplasm surrounding them, while the microglia in the "gitterzellen" phase show large vacuoles, delicate trabeculae and irregularly shaped pyknotic nuclei. The nerve cells of the cerebral cortex and spinal cord show identical globose swelling of their cell bodies. However, in many of these cells in the central nervous system, nuclear detail can be made out.

Fig. 3 (MacMillan). Higher magnification of (B) in Figure 1.

The marked atrophy of the optic nerve, as seen by the small nerve bundles, the disturbed architectural pattern, the apparent connective-tissue increase, and the increased nuclei in the glial septa and the spaces between the bundles in the nerve, is the typical picture of optic-nerve atrophy which is the result of atrophy of the axis cylinders from the abnormal ganglion cells.

Summary

For years it has been generally accepted that lipoid deposits occur in the ganglion cells in amaurotic family idiocy. There are many types of ganglion cells in the central nervous system and in the retina. Among these the bipolar cells of the retina must be classed as neurones or ganglion cells. The globular cells of the internal nuclear layer must be changed bipolar cells because of their location. It is admitted that some may be changed horizontal neurones and others changed displaced ganglion cells or so-called Dogiel cells. The point is that these swollen cells are found in all depths of the internal nuclear layer—inner, middle, and outer layers. It is the changes in this layer which, although described before, because of their clarity and readiness of illustration justify this report. It is not surprising that changes should occur in this layer as the cells are neurones in the same sense as the ganglion cells in the ganglion cell layer.

Cytologic studies of the retina are difficult; we have adhered to methods which do not lend themselves to detailed cytologic

study. New methods of fixation of the retina and improved technical methods must be devised. In this particular case we regret that more detail could not be given of the cell changes. Many of the stains carried out were disappointing because the proper fixative necessary for different stains had not been used.

We should not stop at histologic description of the lesions in amaurotic family idiocy, important though they be, but we should look for metabolic abnormalities in the disease. We ordinarily think that ganglion-cell activity pertains only to nerve impulses and often forget that ganglion cells, like other cells, must carry on cell metabolism. Many neuro-histologists feel that myelin is formed by the neurones when their axis cylinder processes are to be insulated. If this be so, myelin, a complicated lipoid, is synthesized by metabolic processes going on in the nerve cell. Theoretically then, all nerve cells, even though their axones be unmyelinated, may be suspected of some such metabolic activity. It would seem that the abnormal material in the ganglion cells must be the result of an inherited metabolic dyscrasia.

Royal Victoria Hospital.

I am deeply indebted for the coöperation supplied by Dr. William V. Cone, whose knowledge of the cytology of the central nervous system has made this presentation possible.

THE EFFECT OF EXPOSURE TO SUNLIGHT ON NIGHT VISION*

SELIG HECHT,† PH.D., C. D. HENDLEY,‡ PH.D., SHERMAN ROSS,§ PH.D. AND P. N. RICHMOND‖

I. NATURE OF PROBLEM

Reports from North Africa and the South Pacific during the last war suggested that night vision deteriorates after exposure to very strong sunlight, particularly on coral islands. Derman[2] (also reference 7) reported 50 cases of night blindness in the Turkish army, apparently due to bright light. In view of the military importance of this problem, it was decided to investigate the effects of sunlight in a quantitative manner. The problem is a three-fold one. First, is the onset of dark adaptation delayed after exposure to bright sunlight? Second, is the process slowed up so that the threshold is still above normal even after an hour or two in darkness? Third, is the effect of daily exposure cumulative?

The first question has already been answered. The speed of dark adaptation is strongly influenced by the brightness of the preceding light adaptation.[3, 4, 10] Thus, after light adaptation to 100 millilamberts (ml.), the rod portion of dark adaptation appears almost at once, whereas after exposure to 40,000 ml. it does not become evident for 12 minutes.

Previous work[4] also showed that after adaptation to high intensities the final threshold may be delayed out of all proportion to the delay in onset of dark adaptation. For instance, 40 minutes after exposure to 40,000 ml. the eye is still about 0.5 log unit above its normal final threshold. No quantitative data on the cumulative effect of sunlight were known. Our aim, therefore, was to find out how long the threshold remains above normal after exposure to sunlight, and whether such effects accumulate when people are exposed day after day.

II. APPARATUS AND METHODS

The measurements were made with two Hecht-Schlaer adaptometers, model 3. The binocular threshold of a retinal area 7° above the fovea and 3° in diameter was measured. One instrument used blue light of dominant λ 480 mμ., the other used white light. Since the intensities are given in micro-microlamberts in terms of photopic brightness, the thresholds on the two instruments will differ because of the Purkinje phenomenon. Many comparisons showed the average threshold to be 1.20 log unit higher on the white instrument, with little individual variation. All measurements were referred to the blue instrument. Each subject was measured consistently on the same instrument.

In determining a threshold the operator controls the brightness of the stimulus with a neutral wedge, while the subject operates a shutter that gives reproducible 0.2 second flashes. The wedge is first set to give a brightness about 1 log unit above threshold, and the brightness is then reduced in steps of 0.5 to 0.2 log unit, until he fails to see even a faint flash of light. With the threshold thus roughly determined, the operator varies the

brightness in a random way above and below the threshold, always by even tenths of a log unit. The point at which about 3 out of 5 exposures are detected as flashes of light is the threshold. After a minute's rest the procedure is repeated. Almost always, the thresholds agree to 0.1 log unit. When the difference was greater, more determinations were made after a longer rest, until a satisfactory threshold was obtained.

III. The course of dark adaptation following bright outdoor light

Experiments were conducted in New York on the effect of exposures to bright sky on dark adaptation. The subjects looked at the sky for periods of from four minutes to an hour. The brightness varied from 3,000 to 12,000 ml., the limiting factor being the subject's ability to look at the light without undue pain. In the final stage of light adaptation, one eye was closed to reduce the discomfort and to make it possible to look at a brighter part of the sky. Both rod and cone adaptation were followed, using the Hecht-Shlaer model 1 adaptometer,[6] with monocular observation.

At Camp Lejeune, a further study of comparatively short exposures to bright light was made, the sky brightnesses ranging from 3,500 to 16,000 ml., and the time of exposure from 2 to 35 minutes. For comparison, dark-adaptation curves were obtained after exposure to 5 and to 50 ml. In each case, the threshold after one hour of dark adaptation was obtained before the start of the light-adaptation experiment. If the subjects had to be outdoors before this initial measurement, they wore red goggles to prevent uncontrolled exposure to bright light.

Table 1 summarizes the main features of the experiments. Since different subjects were used in the various tests, and there is considerable individual variation, the results for different times and brightnesses are not directly comparable. However, it is clear

enough that, after exposure to bright skylight, dark adaptation is considerably delayed. The significant parts of four representative dark-adaptation curves are shown in Figure 1.

IV. Preliminary experiments on prolonged exposure to sunlight

In these experiments each subject had his threshold measured in the morning after one hour of dark adaptation. The group then spent several hours on an ocean beach in the sunlight. After 2 to 5 hours the group returned to the dark room, and was tested after various lengths of time in the dark. Four groups were also measured the next morning after one hour of dark adaptation. Table 2 gives the results. It is clear that exposure to sunlight delays the course of dark adaptation. There seems to be some residual effect after several hours, and perhaps even overnight.

V. Final experiments at Camp Lejeune

A. Procedure

A series of systematic experiments were set up to determine whether or not daily exposures to sunlight produced any cumulative effect on night vision. We worked with 51 young men with normal night vision. The control group of 20 men was kept at indoor tasks to prevent exposure to bright light. They wore red dark-adaptation goggles whenever they went outdoors during the day. The experimental group of 31 men was sent every day except Sunday to the beach.

On sunny days near noon, the illumination was about 10,000 foot-candles, but because the sand was rather dark—having a reflectance of 0.3 at most—the brightness of the beach was less than 3,000 ml. Viewed from the beach the water was darker than the sand. The sky varied from about 500 to 15,000 ml.

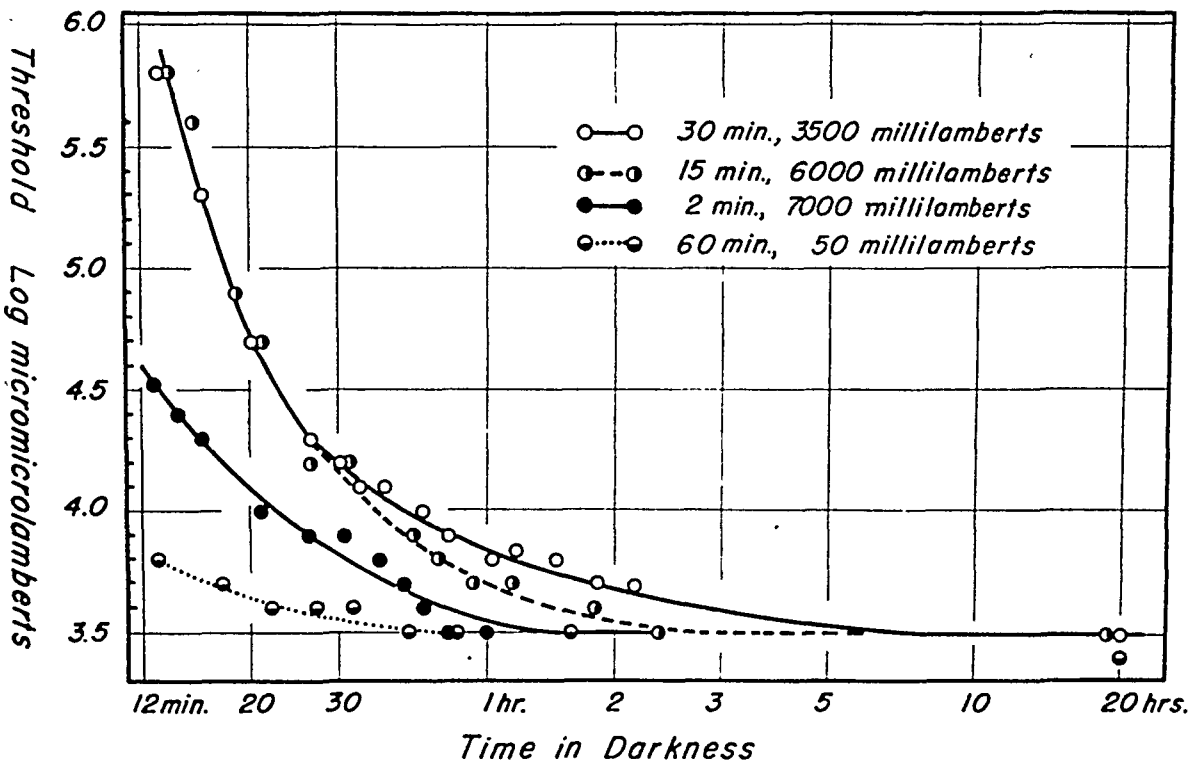

Fig. 1 (Hecht, Hendley, Ross, and Richmond). Dark adaptation after exposure to bright sky.

TABLE 2

EFFECT OF SUNLIGHT ON NIGHT VISION*

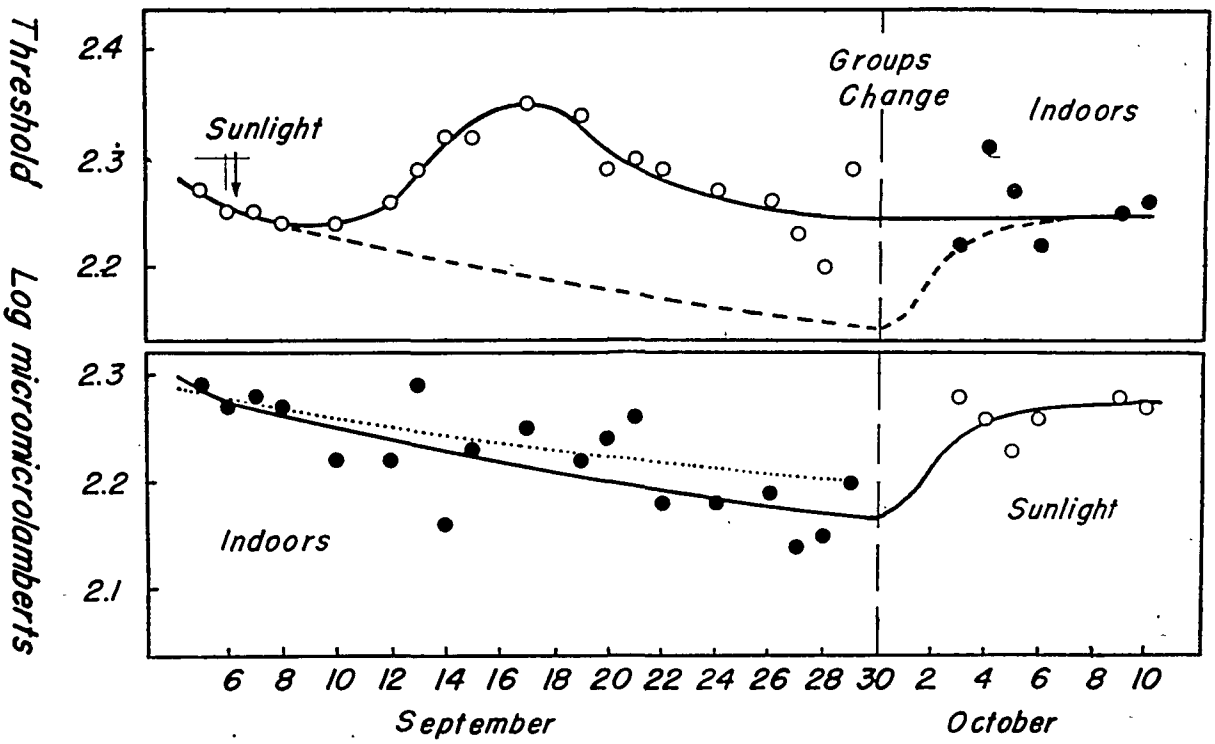
		⅓	¾–1	1½	4½–5	16+
6	2		+0.25	+0.20		−0.02
6	5	+0.85	+0.25		+0.09	
4	2		+0.27		+0.27	+0.16
6	2½		+0.23			
11	2½		+0.19			+0.09
10	5		+0.12			−0.05

* Sky Brightness 3–5×10³ ft. lamberts
Water Brightness 1–3×10³ ft. lamberts
Sand Brightness 1–2×10³ ft. lamberts

At the beach the men were instructed not to close their eyes, or protect them from light in any way. During the first 2 weeks the men were exposed to the sun for about 4 hours, of which two were spent in an open boat going to and from the beach. Later the subjects had about 6 hours of continuous exposure, of which only one was spent in transit. The subjects were dark adapted for one hour before their thresholds were measured.



These procedures began September 5th and continued through September 30th. Af-

ter the morning measurements on September 30th, the indoor and sunlight groups changed places. The X (experimental) group, which had been outdoors every day, remained indoors. The C (control) group, on the other hand, took off their goggles and went outdoors on the beach. This continued until October 10th when the experiment had to be ended.

Indoor Group - - - - Randolph Field Cadets

Fig. 2 (Hecht, Hendley, Ross, and Richmond). Effect of sunlight on morning threshold.

B. Cumulative effects

Table 3 shows the morning one-hour thresholds after a night's sleep and before any exposure to sunlight. There are several ways in which the measurements may be treated, from following each small group to making weekly averages of all groups. We find the results are much the same any way the data are examined. The data are summarized graphically in Figure 2.

Initially the two groups were chosen to have almost identical average thresholds. Actually they differed by only 0.02 log unit. During the course of the experiment, the control group threshold decreases gradually; while the sunlight group threshold rises and then seems to return about to its original level. The decrease in the control group represents the improvement which comes with practice in untrained individuals. It occurs regularly, and is of the same order of magnitude as found here. For comparison, the data for 37 aviation cadets at Randolph Field are shown in Figure 2.

When the two groups were reversed the old control-group threshold (now the sunlight group) began to rise. After three days the rise was almost 0.1 log unit and further exposure caused no significant further rise. The original sunlight group (now indoors) showed practically no change for the 10 days they were protected from light.

In making a quantitative estimate of the changes caused by sunlight, we must include

the improvement shown by the control group. There is no reason to suppose that the sunlight group did not improve in a similar way. Indeed, this group did show a slight decrease in threshold the first few days. Thus the control data provide a base line for the sunlight data. This is indicated by the dotted line under the sunlight measurements in Figure 2.

Another way to show the cumulative effect of exposure to sunlight is to compare the distribution of thresholds before the experiment with those after the two groups diverged. In Figure 3 those comparisons are made, and as before the sunlight group shows a small rise in threshold after 9 days outdoors, even though 4 of these days were overcast. The outdoor group was lower than the control by 0.02 log unit at the start, but is 0.12 log unit higher after exposure. This change is 4.3 times the standard error of the difference between the two means after exposure, and the difference is certainly significant by this test.

C. Daily effects

For 9 days, between September 25th and October 5th, for each group that was exposed to sunshine, we measured the threshold after one hour of dark adaptation in the morning before the exposure, in the afternoon after returning from the beach, after supper, and early the next morning. Each indoor group was measured at the same time. The averages of these nine series of determinations are shown in Figure 4. The one-hour threshold is raised by 0.14 log unit due to sunlight, and this rise does not completely disappear until some time in the night. By the next morning the one-hour threshold is practically the same as the day before.

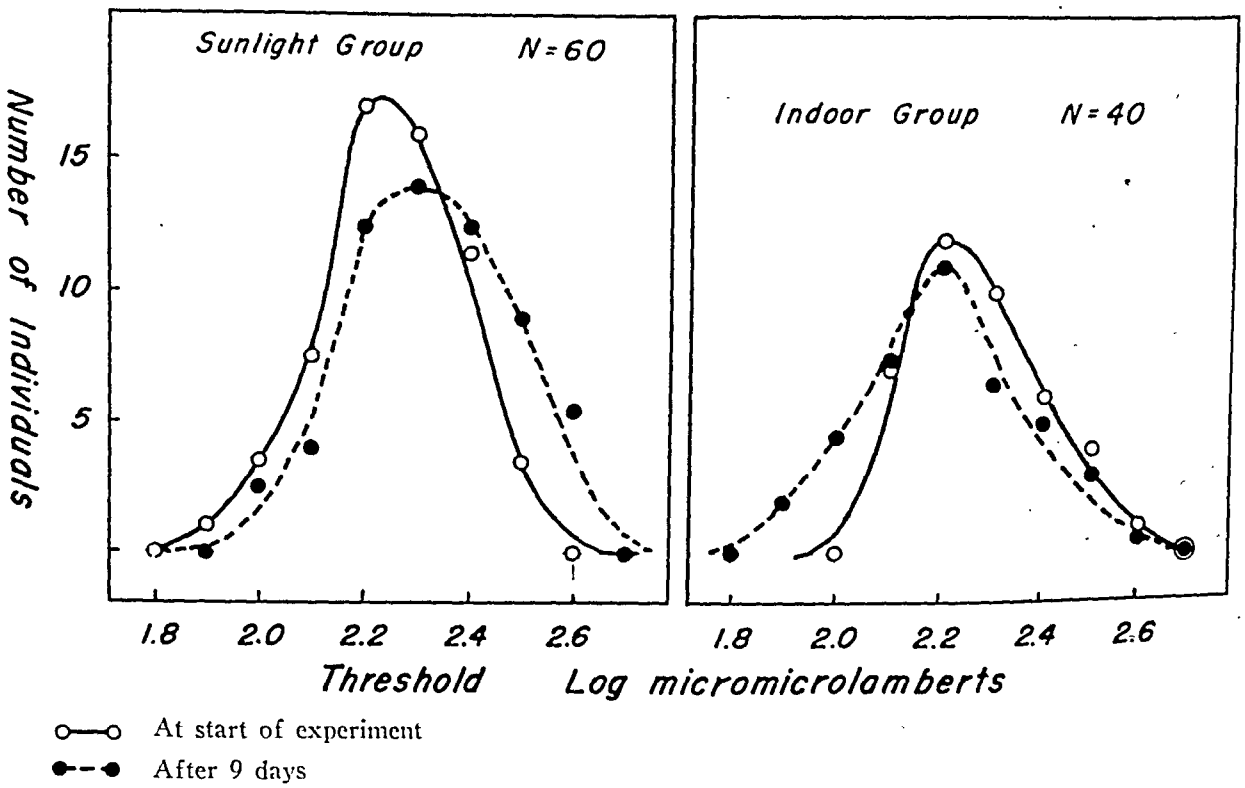

Fig. 3 (Hecht, Hendley, Ross, and Richmond). Distribution of thresholds.

VI. Discussion

From all these experiments we may conclude that night vision is interfered with significantly but not drastically for a period of several hours after a single prolonged exposure to sunlight. Our work also showed that daily exposures to sunlight produced a

cumulative chronic effect on night vision which after 10 days had about the same magnitude as the maximal temporary effect of a single exposure.

This second conclusion has been called into question by two later reports. Clark, Johnson, and Dreher,[1] working at Pensacola, Florida, confirmed the temporary effects of sunlight, and found a threshold elevation of about 0.13 log unit even after a night of dark adaptation. However, they found that "the threshold returns to normal after one day's protection from the sun." Ross, Mueller, and Richmond,[9] at Camp Lejeune, also found temporary effects that did not, however, persist overnight.

In both the Camp Lejeune studies we were handicapped by cloudy weather and by the low reflectance of the beach. The Pensacola workers did not run into these difficulties and, although no brightness measurements are reported, they state that "the bright sunlight and high reflectivity of the sand on the beaches closely approximate conditions of illumination found in the islands of the South Pacific." In view of the importance of determining for certain whether bright sunlight can cause prolonged deterioration in night vision, we feel that further investigations should be made, in tropical or arctic regions.

We may state with assurance, on the basis of the work to date, that daily exposure to bright sunlight for 3 hours or more causes a rise in threshold which is of the order of 0.2 log unit, on the average, during the succeeding night. Such a rise has a substantial influence on night visual performance. It has been shown[5] that a person so affected by sunlight has his night visual acuity cut in half, his range decreased to half, and the contrast which he can just recognize increased by 50 percent by comparison to his normal self. This deterioration in visual function is of about the same order of magnitude as that suffered by an aviator flying at night between 12,000 and 15,000 feet without oxygen.

While is it not our object in this paper to inquire into the physiologic mechanisms involved, we are inclined to believe that it is the visible part of the radiation that is effective. Ultraviolet forms only a small part of the radiation reaching the cornea, and while it can burn this part of the eye, as in snow blindness, it does not reach the retina to any appreciable extent, because of the great absorption of the lens and eye media. Nevertheless, if any further sunlight studies are made, it might be well to exclude the ultraviolet, merely to have the information. Infrared rays, although they comprise over half the radiation on a sunny day and do get through to the retina, are probably also not responsible. We know of no evidence that infrared radiation is harmful unless many times as intense as it is in the brightest daylight. There are cases reported of retinal burns from staring at the sun, but this did not occur in our experiments.

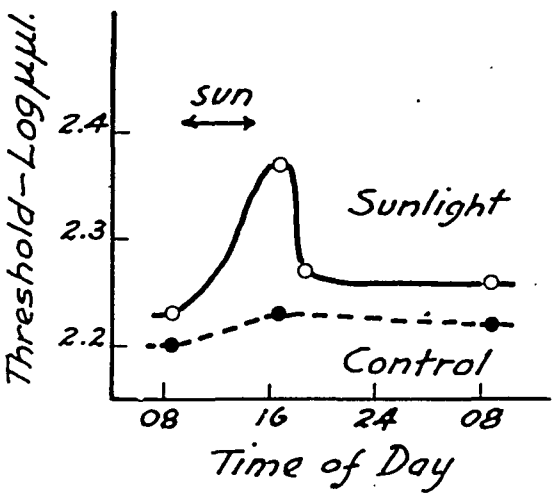

Fig. 4 (Hecht, Hendley, Ross, and Richmond). Thresholds after one hour in darkness.

There exists an extremely simple preventative for avoiding the ill effects of exposure to sunlight, namely adequate sunglasses. Many of the best known and most expensive sunglasses now available are designed for maximum transmission of visible radiation, while cutting out as much as possible of the ultraviolet and infrared. As a result, they trasmit 50 or even 75 percent

of the light. Such sunglasses would be of little value in preventing injury to night vision. It was recommended[5] that glasses should transmit at most 10 percent of the light. The Navy did issue sunglasses that came close to this specification, having a transmission of about 12 percent (Sun, N-1, Contract No. NXsX-66884).[8] Clark *et al.*[1] found that these glasses did indeed protect against the deleterious effects of sunlight on night vision.

VII. Summary

1. Exposures to ordinary sunlight produced temporary and cumulative effects on night vision. A single exposure of 2 or 3 hours delayed the onset of rod dark adaptation by 10 minutes or more, and slowed the process itself so that the normal night vision threshold was not reached for several hours afterward.

2. After repeated daily exposures to sunlight, the delay in reaching the normal threshold persisted overnight, and the threshold after complete dark adaptation rose higher each day for about 10 days and remained at a higher level.

3. This elevated threshold corresponds to an average deterioration of about 50 percent in visual acuity, range of visibility, contrast discrimination, and in the frequency of picking up a target when it is barely visible. The effect shows considerable individual variation, but the average loss in night vision is nearly the same as is suffered by flying at 12,000 feet at night without oxygen.

4. It is strongly recommended that sunglasses transmitting 10 percent or less of visible light be used by all persons who, while working in bright sunlight during the day, will be expected to perform critical night duties soon afterward.

UVEOPIGMENTARY SENSITIZATION*

HAROLD H. JOY, M.D.
Syracuse, New York

SYMPATHETIC OPHTHALMIA

Although anaphylaxis as a cause of sympathetic ophthalmia had been discussed earlier, Elschnig[1] was the first to present a clear description of a workable theory supported by experimental facts. In 1910, he advanced the idea that sympathetic ophthalmia was the result of an anaphylactic reaction in which uveal pigment acted as the antigen. His theory assumed that a perforating wound involving the uvea may cause liberation, dissemination, and absorption of the pigment. Since the uvea is the only structure containing this pigment, he postulated that its absorption produced hypersensitivity to it of the uvea of both eyes. He maintained that further absorption acted as a shocking dose, causing an anaphylactic intoxication of the sensitized uveal tissue of the uninjured eye, and resulted in the clinical picture of sympathetic ophthalmia.

ALLERGIC THEORY

Elschnig's theory was based on complement-fixation studies indicating that the pigment of the uveal tract was the uveal constituent responsible and that it was capable of acting as an antigen in the homologous animal, and that it was organ specific but not species specific. These findings were confirmed by Weichardt and Kummel,[2] and later by Kummel,[3] but were questioned by Rados,[4] Fuchs and Meller,[5] and von Szily.[6] In 1916, Woods[7] repeated Elschnig's work, and, with one minor exception regarding species specificity, confirmed his original results. These experiments were again repeated and confirmed by Nakamura,[8] and later partially confirmed by Kodama.[9] In studies of the mode of absorption of uveal pigment in man, Henton[10] offered further proof of its organ specificity.

Since 1916, Woods has taken the dominant role in the investigation of the antigenic properties of uveal pigment, and the present status of the allergic theory is largely due to the results of his studies. The immunologic properties of uveal pigment have been substantiated, and it has been established that after an injury to the uveal tract, the pigment may be absorbed and produce an immunologic reaction. Woods[11] showed that it was possible to produce uveitis in the fellow eye after intraocular sensitization of dogs with uveal pigment and subsequent inoculation by intraperitoneal injection. He also found that antibodies specific for uveal pigment were usually present in patients whose eys healed normally, but were absent when the inflammation was prolonged and when sympathetic ophthalmia developed.[12] These findings were not entirely confirmed by Fodor[13] who, while he demonstrated the occurrence of such antibodies in many cases, did not concur as to their appearance in specific conditions. He agreed as to their absence in sympathetic ophthalmia, but he found them only irregularly in eyes that healed uneventfully, and also found them in some cases of retinitis pigmentosa and in other diseases of the uveal tract. Gifford[14] failed to find antibodies in four patients, two of whom had sympathetic ophthalmia. With the development of more modern immunologic ideas, Woods[15] later concluded that he had exaggerated the significance of the appearance of antibodies in his earlier studies.

INTRADERMAL SENSITIVITY TEST

Because of the technical difficulties and the delay in the appearance of the antibodies in the complement-fixation reaction, Woods[16] supplanted it by the less complicated and

* Read at the III Pan-American Congress of Ophthalmology, Havana, Cuba, January 8, 1948.

quicker acting intradermal sensitivity test. Using uveal pigment as an antigen, Woods and Little[17] revealed several significant features. They found that true hypersensitivity to uveal pigment occurred only after penetrating wounds of the uveal tract, and that in such cases an unfavorable prognosis could almost always be expected. The response in patients with sympathetic ophthalmia was generally positive, but occasionally a negative reaction was found during acute exacerbations. This led the authors to assume that there may be periods showing a negative phase similar to those found in certain stages of acute tuberculosis, in which the reaction to tuberculin may be negative.

"False positive" test

It has long been noted that occasionally patients with severe traumatic uveitis, who do not develop sympathetic ophthalmia, show a positive cutaneous pigment reaction, the so-called false positive test.[16] Some eyes from such patients have been removed because of the fear of sympathetic inflammation, and others because of pain due to severe uveitis. The pathologic picture in such eyes differs somewhat from that of sympathetic ophthalmia. Nevertheless, at one time consideration was given to the possibility that sympathetic uveitis might have occurred if the eyes had not been removed.[16] Later, it became apparent that this condition did not necessarily predispose to sympathetic ophthalmia, for in cases in which the affected eye was not removed, the fellow eye did not become involved. Woods[16] has long been impressed by the clinical similarity of these cases and he and Little[17] suggested that the condition appeared to be a clinical entity, the characteristics of which are the development of a delayed, severe, recurrent, and chronic postoperative or traumatic uveitis associated with the synchronous development of allergy to pigment.

Histologic studies

The evidence of relationship of uveal pigment allergy to sympathetic ophthalmia received considerable support from Jonas Friedenwald's histologic studies.[18] Since, according to the Elschnig-Woods theory, uveal pigment is the antigen responsible for the pathologic reaction in sympathetic ophthalmia, Friedenwald speculated that pigment granules within the phagocytic cells should be found in the centers of the lesions; for if the disease is allergic, the specific antigens should be demonstrable in the specific lesions.

In his investigation, he found that not only were the epithelioid cells and giant cells of the uveal tract filled with stainable granules, but so were those in episcleral and retinal nodules. The retinal findings were particularly significant, for the picture was quite different from that found in other pigmentary disturbances of this tissue. The characteristic feature was the fact that whenever melanin pigment was deposited in the retina, the granules were engulfed by epithelioid cells and giant cells and surrounded by an inflammatory infiltration which had all the characteristics of the specific lesions of sympathetic ophthalmia.

The presence of these nodules raised the question as to how far the characteristic inflammatory reaction of sympathetic ophthalmia might be considered as due solely to an allergic reaction to the pigment granules. The question was answered by studying histologically the reaction in the skin to a local injection of a suspension of uveal pigment. Friedenwald found that two weeks after injection the histologic picture of the excised skin was identical to that of the ocular reaction in patients with active sympathetic ophthalmia. On the other hand, in normal and insensitive individuals, the picture was quite different. He concluded that the disease had been reproduced in the skin of a susceptible individual by the local injection of the presumed specific antigen. He further concluded that the characteristic pathologic changes found in this disease are compatible with the allergic hypothesis. Alexseev[19] made similar histologic examinations of the excised cutaneous segments in 6 cases, 5 of

which showed clinically positive skin tests. The one clinically negative case proved to be positive histologically.

Desensitization

On the assumption that allergy to uveal pigment is at least a fundamental factor in the production of sympathetic ophthalmia, Woods[16] presumed that, theoretically, this factor should be removable by desensitization with the specific allergin. Using uveal pigment injected intramuscularly he sought to specifically desensitize patients with sympathetic inflammation. As the result of many years' observation involving a comparatively large number of patients, he believes the therapy to be specific and of true value.[17] However, uveal pigment is an insoluble and feeble antigen, and its absorption is slow so that desensitization is a long-drawnout process.[20] Friedenwald[18] obtained a more rapid desensitization by exposure of the skin of the body to ultra-violet light. His purpose was to produce a proliferation of the melanophores of the skin, so that the body might be provided with a readily available and widely distributed supply of pigment antigen.

Comment

Thus, it appears that the proponents of the allergic theory have built up a strong case in support of their contention that uveopigmentary sensitization is the essential element in the production of sympathetic ophthalmia. However, this evidence is not quite as formidable as it first appears. Its cornerstone is the assumption that uveal pigment is the antigenic substance involved in the process. But, in spite of extremely strong evidence that this is true, the fact that some investigators have been unable to confirm its immunologic reaction cannot be ignored.

Even if one accepts the organ-specific properties and antigenic action of uveal pigment, consideration must be given the possibility that the immune response is not specific, but may be due to the absorption of a foreign protein. It is possible that some substance other than the pigment is the antigenic agent. The isolation of uveal pigment is an exacting and complicated process and there is always the chance that it may not be free from other tissue substances or that changes may occur during its preparation.

Moreover, it is a well-known fact, as pointed out by Berens,[21] that allergic individuals give a reaction to certain, sometimes many, antigens, and that those who are nonallergic react negatively to the same antigens. The possibility arises that the former group may have a tendency to react positively and the latter group negatively to uveal-pigment injections.

Whatever the reasons, some investigators[14, 19, 22-25] have not found the uniform clinical results, in using the skin test, noted by the Wilmer group and by Gill.[26] It is possible that this inconsistency may be due to differences in technique or to the use of old pigment. Nevertheless, it clouds the issue regarding uveopigmentary sensitization.

Woods,[15] in presenting the evidence favoring the allergic hypothesis, admitted that his production of experimental uveitis was open to question, and that while he strongly believed the therapeutic response to uveal pigment was specific, it could not be definitely proved. Examination of the published protocols of Woods's animal experiments, and a review of his reports on the therapeutic use of uveal pigment, indicates that the former showed encouraging but inconclusive results, and that the latter left slight doubt as to its specificity.

However, regardless of objection to certain features in the uveopigmentary sensitization hypothesis, the overall evidence is imposing. This theory readily explains the long incubation period of sympathetic ophthalmia, the failure to find any specific organism, and the rather uniform presence of hypersensitivity to uveal pigment. It also explains the infrequent occurrence of the disease, since only a relatively small number of individuals have an allergic tendency.

CRITICISMS OF ALLERGIC THEORY

On the other hand, several factors are frequently cited in the literature as not harmonizing with this hypothesis, and which indicate that something besides allergy enters the picture. As a matter of fact, not all of these factors necessarily conflict with the allergic theory. An example is the appearance of papillitis as an early and prominent symptom of sympathetic ophthalmia, particularly in cases which show little or no uveal involvement. A possible explanation of the participation of the optic nerve in these cases may be the occasional presence of pigment in its anterior regions.[27]

The dissimilarity of the histologic picture of sympathetic uveitis and that of known allergic reactions has been frequently cited as conflicting with the allergic theory. It is true that the histologic changes appearing in sympathetic ophthalmia resemble those produced by infectious agents. However, as pointed out by Friedenwald,[18] allergic reactions play a greater or lesser part in the histologic changes which take place in infected tissue. Although in some instances the tissues are directly injured by the toxin, in others, such as tuberculosis, an allergic reaction dominates the process, and it is this reaction which determines the characteristic histologic picture. If this is true in tuberculosis, it is conceivable that it may also be true in sympathetic ophthalmia. Further evidence of the similarity of allergic reactions and sympathetic disease is provided by Friedenwald's histologic skin studies, and by the fact that a pathologic picture of allergic origin closely resembling sympathetic ophthalmia has been obtained by injection of horse serum into the opposite eyes of sensitized rabbits.[28]

One of the chief criticisms of Elschnig's original theory was his contention that one of the body tissues was capable of acting as an antigen. This was in conflict with the immunologic rule that an animal cannot be sensitized against his own protein, the "horror autotoxicus" of Erlich. However, in the light of our present knowledge of immunology it is conceivable that the organ specific uveal pigment may have an antigenic action in an homologous animal.

The second phase of this hypothesis has also received much criticism. According to Elschnig, after sensitization has occurred further absorption produces the shocking dose causing anaphylactic intoxication. It has been argued that if this were true there would have to be an interval between the sensitizing and shocking doses in which no antigen was in circulation, on the assumption that the state of anaphylactic shock can occur only when the whole of the sensitizing dose has disappeared.[29] This would mean that uveal pigment must be set free from the injured eye a second time, but not until the pigment produced by the original injury has completely disappeared from the circulation: and this would seem to be a most unusual circumstance to occur during the course of traumatic uveitis. This objection is based on the false premise that there must be an antigen-free period between the sensitising and shocking doses. That this is not true may be demonstrated by such conditions as serum sickness, the positive reaction to tuberculin in active tuberculosis, and many other conditions.

Another argument against the allergic theory is that prophylactic enucleation of the exciting eye would be of no value once sensitization had occurred. Instead, the resultant trauma might be sufficient to act as a shocking dose in causing the disease. To me, this argument does not seem valid. Enucleation of the exciting eye should act to prevent the further absorption of uveal pigment from it and thus tend to prevent the occurrence of the shocking dose. Even admission that the trauma caused by enucleation might stir up the uveal pigment enough to produce it, does not necessarily conflict with Elschnig's

contention. For it would seem to be an unusual circumstance, and it could account for the not infrequent occurrence of sympathetic ophthalmia after prophylactic enucleation.

Factors supporting criticisms

There are two factors which provide quite definite proof that sympathetic involvement is not a purely allergic reaction. These are: first, the fact that sympathetic inflammation does not follow nontraumatic uveitis and other conditions in which there is uveal disturbance; and secondly, the occasional occurrence of hypersensitivity to uveal pigment in patients who do not develop the disease.

The occasional appearance of this "false positive" skin reaction led Woods to modify Elschnig's original theory. His present conception is that the development of allergy to uveal pigment apparently sets the stage for the production of sympathetic ophthalmia by disturbing the immunologic defense mechanism, and that it determines the histologic picture, but that some other unknown factor must be present to initiate the onset of the disease.[20]

The most perplexing feature in this theory is the direct inciting cause. The most generally accepted opinion is that an exogenous infection enters the blood stream and becomes localized in the sensitized uninjured eye. It has been suggested that some unidentified organism or virus may be the infecting agent, or that tubercle bacilli become lodged in the eye, or that the reaction is tuberculo-toxic. However, the whole matter is entirely speculative and it is possible that the inciting factor is entirely nonspecific.[30]

Theory of intraocular melanophores

Friedenwald[18] has suggested the novel theory that the additional factor necessary to initiate the inflammatory reaction is a proliferation of the intraocular melanophores which releases the uveal pigment and makes it available for allergic reaction. He explained his hypothesis as follows:

"In some cases following an injury to the eye, the body becomes hypersensitive to uveal pigment. This alone is not sufficient to elicit the disease, for cells containing melanin granules show no abnormal reaction, in their resting state, to the presence of allergic antibodies. When, however, such cells proliferate, they become vulnerable to the antibodies, and undergo autolysis, releasing their melanin granules, which, in time, elicit the allergic inflammatory reaction."

The pathogenic effect of the melanin granules, and especially of the precursors of melanin, was investigated by Spyratos,[31] who concluded that they act as virulent proteins. However, it is improbable that melanin is the actual inciting agent since it is not thought to contain lipoids or fatty acids[32] which are believed to be essential to the production of the type of granulation tissue found in sympathetic ophthalmia.[33]

Variations of Elschnig-Woods theory

Several variations of the Elschnig-Woods theory have been proposed. Oguchi[34] expressed the belief that liberated chromatophores are responsible for sympathetic inflammation. According to his conception, trauma of the uvea frees immune bodies which attack and destroy the neighboring chromatophores until this change takes place in the entire uvea. The liberated and wandering chromatophores, which act as antigen and as allergen, produce an allergic infiltration when they are in sufficient quantity, or the tissue is electively sensitized. If the liberated chromatophores pass on to the other eye, sympathetic ophthalmia ensues. The pathway may be the blood stream, the optic nerve, or the orbital facial venous system.

Marchesani[35] apparently believes that nonspecific bacterial protein absorbed from the eye produces a paired organ sensitivity of the two eyes, making it possible for the bacteria to localize in the second eye. He based

his conclusions on rabbit experiments in which he produced a histologic picture somewhat resembling sympathetic choroiditis in the fellow eye by repeated intravitreal injections of broth cultures of Bacillus subtilis. However, his conclusions are open to serious doubt, for his assumption that the reaction was allergic has been challenged by Iga[36] and Kiyosawa[37] who, separately, repeated the experiments and concluded that the reaction was due to bacterial metastasis. Their contention receives support from the fact that Friedenwald and Rones[38] found lesions almost identical to those described by Marchesani in eyes of patients who had died of general septicemia.

Riehm[39] reported experiments in which he found that repeated intraocular injections of foreign protein (horse serum) produced sensitivity of the fellow eye in pigmented rabbits, but caused no reaction in albinos. He considered the process to be an elective sensitization of paired organs rather than sympathetic disease. He expressed the belief that sympathetic ophthalmia following perforating wounds was due to an unknown infective agent which acts as an antigen only in human uveal tissue, and sensitizes the uvea of both eyes—an anaphylactic inflammatory reaction to a bacterial antigen. On the other hand, he regarded the reaction as purely allergic, with elective sensitization of the fellow eye, in sympathetic inflammation following such conditions as intraocular melanoma and subconjunctival scleral rupture.

Schlaegel[40] repeated Riehm's experiments but used smaller and fewer doses of horse serum. He found a minimal response in the fellow eye and an equal reaction in pigmented and albino rabbits. However, he did not consider that the results of his investigation had discredited the pigment-allergy theory.

In evaluating animal experiments the biologic and immunologic differences between animals and man must be remembered. Samuels[41] has pointed out the dissimilarity of the rabbit and human choroid. In rabbits, apparently, it is constitutionally more resistant and the circulation more active in carrying away toxins. As a result, irritative lesions cause lymphocytes to appear, but pus cells are notable for their absence. It is not difficult to make a mistaken histologic diagnosis of sympathetic ophthalmia in rabbits, due to the fact that groups of capillaries and endothelial buds in the dense lymphocytic infiltrations may simulate epithelioid cells.

Discussion

Allergy to uveal pigment is only one hypothesis concerning the pathogenesis of sympathetic ophthalmia, but time does not permit discussion of other theories, some of which are built on firm foundations. I have endeavored to review some of the progress and the present status of what up to now is probably the most complete and most carefully worked out theory of this disease. It seems probable that sensitization to uveal pigment plays at least some part in the production of sympathetic ophthalmia but to what extent, time and future studies alone will tell.

Vogt-Koyanagi Syndrome and Harada's Disease

The occasional occurrence of alopecia and poliosis in sympathetic ophthalmia and in other types of uveitis has long been noted. Nettleship, many years ago, suggested that similar pathologic processes were probably present in sympathetic disease and in destructive iridocyclitis with poliosis.

Two types of bilateral nontraumatic uveitis possessing most of the characteristics of sympathetic ophthalmia have been identified. These two conditions are probably related, and according to many authors they comprise a single entity. In one, the Vogt-Koyanagi syndrome, the uveitis is associated with alopecia, poliosis, and, frequently, pigmentary changes of the skin and auditory disturbances. The other milder syndrome, Harada's disease, is characterized by a ser-

ous choroiditis which produces temporary detachment of the retina.

Only a few eyes of patients with the Vogt-Koyanagi syndrome have been examined histologically. These have shown a similarity to sympathetic uveitis, but with the exception of the case studied by Matsuoka[42] there has been an absence of epithelioid cells and giant cells. Because Harada's disease is apparently self limiting, histologic material has been available in only one case in which there was secondary glaucoma necessitating iridectomy.[43] Pathologic examination showed giant cells of the Langhans type. However, the disease has been reproduced in rabbits' eyes by the injection of cerebrospinal fluid and other substances from patients with this condition. The histologic picture resembled sympathetic ophthalmia except for the absence of giant cells.[44]

Because of the histologic and clinical resemblance of these two conditions to sympathetic uveitis, attempts have been made to explain them on an allergic hypothesis. The basis for this idea was Elschnig's[45] contention that alopecia and poliosis in association with sympathetic ophthalmia resulted from the antigenic effect of uveal pigment, the hair being involved because of its richness in pigment.

Peters[46] speculated that the disturbance of hearing in the Vogt-Koyanagi syndrome might be due to sensitivity of the pigment in the basilar membrane of the labyrinth, and Cramer[47] attempted to explain the hair disturbances on the same basis. However, the dearth of pigment in the basilar membrane and the lack of knowledge of its physiologic function caused Koyanagi and others to object to Peters' explanation. Koyanagi[48] explained further, that hearing defects usually occur before uveal pigment can have exerted its antigenic action. Weskamp[49] suggested that it might be possible to explain all of the symptoms of the syndrome by anaphylaxis, since the majority of them originate in tissues rich in pigment. Oguchi[34] impressed by the similarity to sympathetic ophthalmia expressed the belief that the syndrome might be the result of liberated and wandering chromatophores which act as allergens.

Rosen,[50] who is apparently strongly convinced that the Vogt-Koyanagi syndrome and Harada's disease are a common entity and are due to allergy to uveal pigment, suggested that these two conditions probably represent different degrees of involvement in individuals of variable sensitivity. He speculated that in Harada's disease an immunity is soon developed to a severe allergic reaction; whereas, in the Vogt-Koyanagi syndrome the allergic reaction is much less acute, with practically no immune response except when stimulated.

In the four cases of the Vogt-Koyanagi syndrome in which cutaneous sensitivity tests to uveal pigment have been made, a positive reaction occurred in only one.[51, 52] It was assumed that the negative reactions were due to desensitization, as all of these cases had already passed the acute stages when the test was done. However, as pointed out by Rados,[53] this explanation is not entirely adequate since the positive case was also of rather long standing.

It is apparent that an allergic basis for the production of the Vogt-Koyanagi syndrome and Harada's disease is far from established. In spite of the clinical and histologic similarity of these diseases to sympathetic ophthalmia, it is possible that the etiologic causes are entirely different. Beauvieux and Bessiere[54] concluded that rather than indicating a common etiology, it suggests that different viruses may have similar tissue affinities. While it is tempting to speculate that allergy to uveal pigment at least enters the picture, further proof must be provided.

THE ETIOLOGY, SYMPTOMATOLOGY, AND TREATMENT OF JUVENILE GLAUCOMA*

ORWYN H. ELLIS, M.D.
Los Angeles, California

It is the purpose of this paper to present the etiology, symptomatology, and treatment of juvenile glaucoma. This condition has been usually regarded as entirely familial; however, I now have five patients between the ages of 15 and 26 years, in whom there is no history of familial tendency. With the introduction of gonioscopy and goniotomy the condition can now be properly diagnosed and operation, when indicated, carried out under direct observation.

To Troncoso and Barkan[1] we owe a debt of gratitude, since it is through them that our knowledge and understanding of glaucoma has been greatly increased with the introduction to ophthalmology of the routine and simplified use of the gonioscopic examination. Now that we can see directly the angle of the anterior chamber, its trabecula, and any obstruction to the outflow of aqueous, our understanding of the filtration angle has been increased. With the gonioscope lens we can view the block of the angle in congenital glaucoma. Likewise, with a clear view of the angle, adult cases can now be classified anatomically into narrow- and wide-angle glaucoma, instead of being classified according to the previous clinical groupings.

ANATOMY OF ANTERIOR CHAMBER

Gonioscopy is so thoroughly an anatomic examination that a review of the anatomy of the anterior-chamber angle is in order. As the cornea passes into the sclera, its inner surface makes an angle with the anterior surface of the iris. Approximately at the apex of this angle in the cornea is normally located the canal of Schlemm. The canal is separated from the anterior chamber by the trabecula, the interstices of which are lined with endothelium. The corneal endothelium, according to Reese,[2] as well as some of its cuticular product, is continued from the cornea to cover the interstices of the trabecula. The structure of a trabeculum, therefore, is a central collagenous fibrous strand around which, as a thin glass membrane, is a cuticular product and this in turn, is covered by the endothelium, which fills the interspaces and/or forms a Descemet's-like membrane along the inner surface of the angle.

With the gonioscope lens in place, as one approaches the anterior-chamber angle from the corneal side, a prominence is first seen which is the anterior border ring of Schwalbe. This constitutes the termination of Descemet's membrane. Between this and the next landmark, which is the white line of the scleral spur, can be seen the individual fibers of the trabeculum running in meridional and circular directions. This zone of Schlemm's canal appears as a faint grayish or occasionally pinkish band. In deeply pigmented eyes, the trabecula is seen to be coated with pigment granules, and the trabeculae then appear dark brown.

As so well described by Barkan,[3] lying directly on this surface there can be seen a few very delicate branching trabecula, which are an extension of the anterior surface of the iris and extend to the posterior corneal surface. These represent that filamentous portion of the network of the angle which anatomists describe as the uveal meshwork. If the iris is removed from the ciliary body in the wet specimen, the anatomist refers to that portion of the meshwork which remains connected to the ciliary body as the scleral mesh, and the very thin portion remaining attached to the iris as the uveal meshwork.

* Presented before the Mexican Association for the Prevention of Blindness, Mexico City, August, 1947.

Teased preparations also show these fibers. Still following around the chamber angle, there is normally seen the dark granular band of the ciliary body, only visible with a wide-open angle. Adjoining this is the anterior surface of the iris.

In juvenile and congenital glaucoma the normal appearance is considerably altered, and none of the usual landmarks can be seen. With the gonioscope lens in place, the anterior chamber is of normal depth, but the angle is everywhere seen to be filled with tissue obstructing the view of even the anterior border ring of Schwalbe. This anomalous filtration angle network is normally present in the fetus until the sixth month and is known as the pectinate ligament. The word pecten means "comb" and refers to the fact that its strands are like the teeth of a comb which has been bent into a circle with the teeth pointing inward. These strands are best developed in horses, seals, and other animals (Walls),[4] where there may be teeth-like processes in several meridians forming a fan somewhat like the situation in reptiles. In horses they are continuous with and identical to the material of Descemet's membrane.

Microscopically in the human eye are seen strands of trabecular tissue or even a mass of considerable density stretching across and blocking the angle of the anterior chamber (Parsons, 1904).[5] This is a persistence of the fetal condition wherein both the sclera and the uveal portions of the trabecula persist, according to Duke-Elder.[6] The etiology of the condition is, therefore, due to the deformities of the angle of the anterior chamber—a persistence of the prenatal or prehuman condition—preventing the free drainage of the intraocular fluids, and thus leading to increased pressure in the eye. This is a developmental abnormality of the mesoderm in the region of the corneoscleral junction. Verhoeff[7] examined two cases of juvenile glaucoma, microscopically, and found in each a defective filtration angle similar to that found in hydrophthalmia.

Hereditary factors

Stokes[8] writes that if it is true that congenital glaucoma (hydrophthalmia) and glaucoma of the hereditary type are essentially the same disease with the same underlying pathogenesis, then the former variety should arise commonly among the offspring of glaucoma patients. There is as yet little evidence that such a sequence is potential. When it does occur it is of interest because it links up the two types.

Lohlein[9] reports a family in which the youngest of the four sisters had hydrophthalmia and the three others had juvenile glaucoma. Scheerer[10] and Korte[11] report families having hydrophthalmia and juvenile glaucoma, and glaucoma simplex with hydrophthalmia, respectively. These cited relationships between the two groups point to an underlying genetic cause leading to a failure (more or less complete) of development of the filtration angle. If the failure is complete, congenital hydrophthalmia results. If it is incomplete, the drainage will be maintained for a variable time, until the sclerosing changes of adult life can no longer be compensated.

Stokes[8] found that when hydrophthalmia is transmitted it appears as a simple recessive; that is, it will not develop unless two conductors of the disease have offspring. Hereditary glaucoma appears as a simple dominant in practically all published pedigrees. Either parent who transmits the disease is usually affected. The chance that an offspring of a glaucomatous person would be similarly affected is in theoretical ratio of 50:50. The chance that an offspring of normal persons would be affected appears to be negligible. Consanguinity does not seem to be a factor.

Age of onset

The age of onset of increased pressure varies in reported pedigrees. The onset of the disease may occur in infancy (hydrophthalmia), early in youth (juvenile glau-

coma), or in adult life. The importance of heredity in glaucoma is as yet not known. Therefore, in these congenital glaucoma types it behooves us to be on the alert for the occurrence of other cases in the family. Keerl[12] analyzed the cases of the University of Leipzig and found heredity to be a factor in 18 percent of cases of juvenile glaucoma. The age grouping was as follows: from 6 to 15 years, 14.8 percent; from 16 to 25 years, 37 percent; and from 26 to 35 years, 48.3 percent. The age of onset in the reported pedigrees varies from 16 to 30 years in families reported by Stokes,[8] Shumway,[13] Calhoun,[14] Courtney and Hill,[15] Bell,[16] and others. According to Allen,[17] 30 years appears to be the upper limit of age of onset.

Regarding the lower age limit for juvenile glaucoma, Anderson[18] uses distention of the eyeball. Thus he writes that due to glaucoma a congenital defect may be classified as juvenile, if it fails to develop until the eye is no longer distensible. The corneal measurements in juvenile glaucoma are all within the limits of normal.

Date of onset

The date of onset of juvenile glaucoma is, in many cases, indeterminate. Thus the reduced age of onset in the younger patients reported could be due to more prompt diagnosis, and must not be taken as a proof of a general tendency to anticipation of the disease, although some anticipation has been reported (Allen[17]). Anderson[18] states that in 87 percent of cases of hydrophthalmia the diagnosis was made before the age of one year.

Cases of juvenile glaucoma are usually chronic; however, the author has seen one patient, aged 26 years, with an acute attack, and a second with a history of a recent acute attack. Allen[17] reports that 18 percent of cases of juvenile glaucoma have acute episodes. He states also that juvenile glaucoma tends to occur more frequently in patients with dark irises.

Relation to myopia

It is still uncertain whether the myopia found in hereditary glaucoma is entirely secondary to the increased intraocular pressure or whether the relation is one of a correlated inheritance similar to that between myopia and other ocular anomalies. According to Stokes,[8] a high intraocular pressure no doubt is a factor in the production of myopia because of the elasticity of the eyeball. The onset of the myopia could even prove compensatory to the high tension changes of glaucoma. Myopia is seldom present in senile glaucoma, but is common clinically in juvenile glaucoma. According to Duke-Elder high degrees of myopia and even hypermetropia are frequently found.

Myopia, according to Parsons[19] is due to the following causes:

1. Decreased corneal convexity.
2. Decreased convexity of lens due to stretching of the suspensory ligament.
3. Displacement of the lens backward—could be due to elastic sclera.

The incidence of myopia in hereditary glaucoma, which averages about 60 percent in all reported families, is sufficiently great to suggest that the hypertension has been influential in producing the bulbar distention and the altered refraction. The occurrence is certainly more than normal and cannot be accidental or incidental.

Influence of race and sex

Stokes[8] found that females are affected a little earlier than males, which is also true of patients with nonhereditary adult glaucoma.

There is no definite racial factor in these cases according to Courtney and Hill.[15] The predisposition of the more nervous or unstable races to acute glaucoma does not seem to hold for the juvenile disease, which is usually of the chronic type.

It is certain that the age limits in glaucoma vary from person to person, as well as in different periods of life. This is even

more true of juvenile than adult glaucoma, and may partly explain the lack of sustained and fixed manifestations of this disease.

Symptoms

By far the most frequent complaint is headache, which is very severe, frequently recurring, usually quite persistent, not relieved by aspirin, present more often in the mornings, and which leaves upon retiring.

Another early symptom, according to McKee,[20] is colored rings around lights—seen first at intervals, then present constantly. Later a sense of fullness or pain in the eye develops. Often these patients give the history that for years they have noticed that their pupils are abnormally large. In the examination, the cornea is usually clear and lustrous; or rarely, if the tension is high, it is steamy. The anterior chamber is always deep, and the pupils are moderately dilated. The disc is usually normal, but may appear slightly pale. No cupping has been seen by me.

Visual fields

The visual fields often show contractures resembling adult glaucoma.[21] The intraocular pressure is rarely found to be elevated, but shows considerable fluctuation, often varying 10 mm. Hg (Schiøtz) from examination to examination. A high intraocular pressure finding is the exception rather than the rule, thus the diagnosis lies entirely with the use of the gonioscope lens. In megalocornea a large expanse of ciliary body is seen, and the normal appearing drainage angle is clearly visualized. This is in contrast to the juvenile glaucoma angle in which the landmarks are covered with dense tissue.

Duke-Elder[6] stated that the condition could stabilize itself in early youth, which could be explained by a stretching process opening up the trabeculae of the angle of the anterior chamber, or by the atrophy of the persistent embryonic tissue in this region. However, this tissue, in most cases, produces embarrassment to drainage.

Verhoeff[7] stated that in juvenile glaucoma the outflow was not completely cut off, at least at first, and, therefore, in early life there is not enough increased intraocular pressure to enlarge the globe; whereas, in hydrophthalmia the pressure is sufficient to do this. Different grades of hydrophthalmia are often present in the same patient, as the condition in one eye may be considerably more advanced than in the other eye. Thus juvenile glaucoma and hydrophthalmia could simply represent differences in degree of the same condition, and Lohlein stated that juvenile glaucoma is a form of hydrophthalmia in which the congenital anomaly of the chamber angle is not sufficient to produce a full-blown hydrophthalmia.

Case reports

At this time I wish to present the case histories of three patients which are in addition to the cases of two patients, aged 15 and 26 years, previously reported.

Case 1

History. M. Q. K., a Chinese physician, aged 26 years, was first examined on December 20, 1946, with the history of an acute attack of glaucoma in the right eye in April, 1945. The present attack began three hours previously with pain, headaches, halos, and blurring of vision of the right eye. He had started using miotics intensively since the onset. There was no history of glaucoma of any type in the family.

Examination. O.D.: Vision, uncorrected, was counting fingers at 3 feet, corrected to 20/70 with a −8.25D. sph. ⌒ +1.25D. cyl. ax. 85°. Tension was: 25 mm. Hg (Schiøtz). The disc showed good color. Fields were normal. O.S.: Vision, uncorrected, was counting fingers at 3 feet, corrected to 20/25 with a −8.0D. sph. ⌒ +2.0D. cyl. ax. 93°. Tension was 28 mm. Hg (Schiøtz). The disc showed good color. Fields were normal.

Gonioscopic examination. The angle was everywhere seen to be blocked with tissue

and very heavily pigmented. No normal angle landmarks were visible.

Diagnosis. Juvenile glaucoma, bilateral, subsiding acute attack in the right eye.

Operation. Under morphine-hyoscine anesthesia and novocaine, locally, a goniotomy was performed as described in a previous paper.[21] More than one fourth of the circumference of the trabecular area was incised on the nasal side of the right eye.

Note. Eight months after this operation an additional acute attack occurred with subsequent goniotomy. Three months afterward a fourth attack of glaucoma suddenly appeared, again following an entirely normal intervening period. A more extensive goniotomy was done following which the tension has remained below 20 mm. Hg. The patient is using miotics only at bedtime. Between the 3rd and 4th operations on the right eye, a goniotomy was done on the left eye as a prophylactic procedure since the tension had occasionally risen above 20 mm. Hg and the gonioscopic appearance of the angles of the two eyes were identical. The corrected vision remains 20/20 in each eye with full fields and normal size of blindspots.

This patient has now been under observation for six months. The tension averages 16 mm. Hg (Schiøtz) in each eye. There have been no further glaucoma symptoms. Premature presbyopia is present, requiring a +1.0D. sph. reading addition.

CASE 2

History. B. O., a white girl, aged 19 years, was first examined on March 8, 1947. She complained of very severe headaches for the past five years. There had been occasional blurring of vision of the right eye for the past two years; however, recently the blurring had been followed by intense headaches. For the past three months the headaches occurred daily. She had never noted any halos. There was no history of glaucoma of any type in the family.

Examination. O.D.: Vision, uncorrected, was 10/200 corrected to 20/20 with a −2.5D. sph. Tension was 21 mm. Hg (Schiøtz). The disc showed good color and the fields were normal. O.S.: Vision, uncorrected, was 10/200 corrected to 20/20 with a −2.25D. sph. Tension was 19 mm. Hg (Schiøtz). The disc showed good color and the fields were normal.

Gonioscopic examination. In each eye, about one third of the circumference of the chamber angle was seen to be occluded with tissue, and none of the normal landmarks could be seen in that area. The rest of the angle was normal with only scattered areas of pectinate ligament occluding the angle.

Course. On a later visit the tension, after using prostigmin, was: O.D., 10 mm. Hg; O.S., 19 mm. The patient was continued on prostigmin (2½ percent) twice daily in each eye, and the tension averaged 16 mm. Hg, examined at different times of the day. One headache occurred three weeks after the original examination. Since then there have been no further headaches and no blurring of vision. She has been followed for five months without any recurrence of symptoms.

CASE 3

History. M. L. B., a white girl, aged 15 years, was first examined on February 8, 1947. She complained of headaches and dizziness for the past year. Recently the vision had been blurred in the left eye, and there was also pain over the left eye which had been accompanied by vomiting. There was no history of glaucoma of any type in the family.

Examination. O.D.: Vision was 20/30, not improved with any lens. Tension was 16 mm. Hg (Schiøtz). The disc showed good color. The blindspot was slightly enlarged; the periphery was full. O.S. Vision was 20/25, not improved with any lens. Tension was 19 mm. Hg (Schiøtz). The disc showed good color. The blindspot was about twice normal size; the periphery was full.

Gonioscopic examination. The nasal half of the circumference of each eye was filled

with tissue, and scattered areas were present in the temporal portion.

Course. Prostigmin (5 percent) was prescribed to be used morning and night in each eye. She returned in one week without any ocular complaint, not even headache, and she has been comfortable since the first visit. The vision is 20/20 in each eye and there is no refractive error. The tension has averaged 14 mm. Hg in each eye. The blindspots have returned to normal size and there have been no further glaucoma symptoms. The medication was reduced to prostigmin (2½ percent) at bedtime.

Comment

In one patient with acute glaucoma, the eyes have remained normalized following bilateral goniotomies. The two other cases, both young girls, have maintained normal tensions and have been relieved of symptoms with the use of prostigmin. Vision improved in one case and the blindspots returned to normal size. This recovery of field loss was also present in the two previously reported cases, both patients having maintained normal intraocular pressure following bilateral goniotomies.

Confirming Barkan's recommendation, I have repeatedly found that, in the treatment of juvenile and congenital glaucoma, prostigmin is the drug of choice and that pilocarpine and eserine are regularly without effect in normalizing intraocular pressure. Postoperatively in one patient,[21] prostigmin caused an elevation of pressure, and Allen[17] reports a similar case, also postoperatively.

Discussion

When the diagnosis of glaucoma has been made, especially in the juvenile and congenital types, careful family history and investigation should be carried out, as the condition can be definitely diagnosed with gonioscopic examination. In none of my cases was there any familial history of glaucoma. One must be constantly on the lookout for juvenile glaucoma in young adults, especially in myopic individuals who complain of severe headaches. It is to be noted that two of these three patients were myopic. Often a history of blurred vision with the headaches is obtained.

I have been unable to find previous reports of the successful use of goniotomy in juvenile glaucoma. It would seem to be indicated in cases with acute rise in intraocular pressure, or in patients in whom symptoms and/or tension is not completely controlled with prostigmin.

No report of the gonioscopic examination of the angle in juvenile glaucoma was published before Allen, in 1942,[17] described fine iris processes with fingerlike or weblike projections extending anteriorly toward the limbal portion of the cornea.

As Reese[2] has stated, the corneal epithelium is capable of producing a cuticular product or glass membrane as exemplified by Descemet's membrane. The endothelium retains its ability to produce the cuticular product throughout life, but does not manifest this potentiality except under certain provocations.

For instance, as a sign of senescence, excrescences of Descemet's membrane are frequently produced in the periphery, as Henle's warts; also, as a senile change, Descemet's membrane may become thickened. The excrescences and the thickening may occur in an aggravated form over the entire membrane and produce the conditions of cornea guttata and dystrophia endothelialis corneae.

We also know that a variable amount of pectinate ligament may be congenitally present in eyes. Therefore, is it not safe to assume that in some adult eyes, with the angle partly filled with remnants of embryonic tissue, the deposition of the cuticular produce as a senile change overcomes the final pressure compensatory mechanism in an already somewhat embarrassed angle, and glaucoma results? The formation of the cuticular product thus is the secondary change super-

imposed on a congenital malformation.

Or, might it not be entirely possible that in other cases this tissue in the chamber angle in an adult eye suddenly contracts producing a large area of narrow or even occluded chamber angle, thereby causing embarrassment of the drainage system? Certainly, this is not the answer to the etiology of many cases in which narrow-angle glaucoma occurs. In some instances we can follow the formation of adhesions with the gonioscopic lens. Any glaucoma, Reese states, with increased pressure, will develop anterior synechias, and thus the later stages, which are the ones usually studied pathologically, could entirely mask the primary condition.

Anderson,[18] in 1939, stated that no absolute distinction can be made to separate juvenile glaucoma from hydrophthalmia (congenital glaucoma), on the one hand, and senile glaucoma on the other. It is probable that at one end of the scale—that is, in early life, an innate defect in structure was the cause of hypertension and that degeneration was merely a secondary phenomenon. At the other end of the scale, raised tension could be due, almost entirely, to various degenerative changes associated with old age, and inherited defects would play a minor part.

There could be then an intermediate group in which both factors would be at work in varying degrees. One wonders then how much of the shallowness of the anterior chamber seen in congestive glaucoma and in glaucoma of old age is due to secondary inflammatory and degenerative changes and is, therefore, a sequel to rather than a cause of increased pressure.

I feel certain that juvenile glaucoma is due to the same etiologic condition as congenital or infantile glaucoma; that is, a congenital remnant of pectinate ligament blocks the anterior-chamber angle and thereby produces increased pressure. That varying amounts of pectinate ligament do occur congenitally and persist in eyes is well known. Therefore, it is logical to conclude that juvenile glaucoma cases are those in which congenital tissue remnants are present, but in which the tension had remained normalized or nearly so for years, at least to adolescent life. At this time, some, as yet unknown, event occurs and the chamber angle becomes blocked, or at least partly so, and glaucoma ensues. By this time, of course, there can follow no globular enlargement as the tissues are now no longer distensible. In the adult with congenital tissue remnants of smaller amounts, it would be safe to assume a similar mechanism could be at work with the same end result, glaucoma.

Although my patients have shown no familial tendency to glaucoma, most cases of juvenile glaucoma have been reported as hereditary glaucoma with long family histories. The outcome has heretofore been almost universally poor with conservative or operative treatment. With the reintroduction of goniotomy and the utilization of prostigmin, the outlook has considerably improved. I now have five cases with tension completely normalized.

The technique of goniotomy was reported by Barkan[22] and modified by me[21] with the introduction of a new direct-contact operating lens. Using this method, an incision can be made into the area of the trabeculum under direct observation. Good results were obtained in both juvenile and congenital glaucoma when the operation was performed early in the disease, while the glaucoma was still in the compensatory stages; that is to say, before irreversible secondary anatomic and pathologic changes had occurred.

Thus we now know the underlying etiology, symptomatology, and treatment of this disease. The only gap in our knowledge is the full understanding of the factor that finally upsets the compensatory mechanism and produces the actual onset of the condition.

The eyes of youth ordinarily contain an adequate pressure compensatory mechanism

but once that compensatory mechanism fails, secondary anatomic changes result, which in turn lead to further rises in tension and an amazingly rapid progression of all features in this disease.

The term juvenile glaucoma has been comparatively rarely used in the literature, and this paper is a plea for the clearer understanding and proper recognition of these cases. With the increased, widespread use of the gonioscope lens these patients will receive the correct diagnosis and early treatment, thereby preventing acute attacks in most cases, with the result that many eyes will be saved from blindness.

SUMMARY

Juvenile glaucoma is due to a congenital remnant of pectinate ligament, which can be clearly seen with the gonioscopic lens, blocking and covering over the angle of the anterior chamber, the same tissue that causes hydrophthalmia or congenital glaucoma. Its possible relationship to adult glaucoma is discussed. Goniotomy and/or prostigmin have been found to control this condition adequately. No familial tendency to glaucoma in the cases herein presented was observed. A plea is made for early recognition of this disease.

SYMPATHETIC NERVOUS SYSTEM AND INTRAOCULAR PRESSURE*

NORMAN S. JAFFE, M.D.
Brooklyn, New York

Within recent years much effort has been exerted in implicating the sympathetic nervous system in the causation of glaucoma. It has been known that alterations in the sympathetic pathways will produce fluctuations in the intraocular pressure.

At one time cervical sympathectomy was the vogue in the treatment of glaucoma.[1] Some have claimed success with irradiation of the cervical sympathetic ganglia. Bloomfield[2] showed that the aqueous of the eyes of glaucomatous patients showed a "parasympathetic deficiency" when exposed to an isolated frog's heart. This may be termed a "sympathetic excess." Schoenberg and Lowenstein[3] have attempted to show with the aid of pupillography that central autonomic structures are involved in glaucoma. Demonstration of this derangement has proved to be of considerable value in the early detection of glaucoma.

It is well known that an attack of glaucoma may be initiated by some emotional upset. Many patients with glaucoma are said to be sympathicotonic. Parasympathetic stimulation and parasympathomimetic agents are efficacious in the therapy. None of the proof may, as yet, be considered undeniably positive. It seems fairly certain, however, that the intimate association between the sympathetic nervous system and intraocular pressure is more than mere coincidence and its role in the etiology of glaucoma, although vague at present, is especially formidable.

The sympathetic nervous system may alter the intraocular pressure in any one of three ways:

1. Effect on general blood pressure.
2. Effect on the minute intraocular vessels.
3. Effect on the unstriped palpebral, ocular, and orbital muscles.

Sympathetic nervous stimulation combined with the subsequent hormonal mechanism (adrenalin) will cause an increase in blood pressure. However, associated with this there is a marked generalized vasoconstriction. Some regions respond with a more profound constriction than others. The skin vessels represent the ultimate in this vasoconstriction. For some reason the ocular vessels exhibit a relatively weak response and consequently offer a poor barrier to the increased tension in the general vascular bed. This accounts for the initial passive rise in intraocular pressure as a result of an increase in general blood pressure.

However, after more prolonged or pronounced sympathetic stimulation the blood-adrenalin level increases still further. Vasoconstriction now becomes effective and the intraocular pressure begins to fall. Thus the pressure will not fall until the intraocular arterioles respond to the increased circulating adrenalin.

The effect on the unstriped musculature must also be considered. It is certainly true that this factor assumes more prominence in an experimental animal, such as the cat, than in a human being. Nevertheless, the effect of stimulation or paralysis of Müller's palpebral muscle in a human being is not without important consequences concerning variations in intraocular pressure. The greater development of the smooth peribulbar musculature and the unstriped muscle in the floor of the orbit in the experimental animal make this consideration more prominent in alterations of ocular tension due to sympathetic nervous-system factors.

In studying the effect of adrenalin on the intraocular pressure, Duke-Elder[4] devised a method of divorcing the arterioles of the eye

* From the Department of Ophthalmology, Jewish Hospital of Brooklyn. This work was supported by a grant from the George Beldock Foundation.

from the effects of the generalized increase in blood pressure. He used the perfused head of a laboratory animal. He noted that small doses of adrenalin (1:10,000) caused an increase in intraocular pressure due to capillary dilatation. Larger doses (1:1,000) produced a variable effect. There was a fall due to effective vasoconstriction or a rise due to contraction of Müller's muscle. The latter usually occurred first and was relatively short lived. The vasoconstriction was more prolonged and consequently there was a drop in tension. It is repeated that these are the effects when the influence of the general blood pressure is made nonexistent.

It has been shown by many [5-8] that stimulation of the cervical sympathetic in animals will cause a sharp rise in intraocular pressure due to smooth muscle contraction. This is followed by a fall in pressure due to vasoconstriction. Section of the cervical sympathetic, on the other hand, has not been so clear cut. Some[9-11] have said there is a fall in pressure; others,[12] a rise. At any rate, it may be safely stated that the sympathetic tonus regulates the pressure of the eye in such a way that factors which ordinarily influence the tension will exert a more marked effect when the sympathetic tonus is eliminated.

Adler, Landis, and Jackson[13] showed that increases in general blood pressure cause an increase in intraocular pressure in the normal eye and a more marked increase in the eye devoid of its sympathetic supply (cervical sympathectomy). They refer to this as the "protective action of the cervical sympathetic." Adler[14] states that after cervical sympathetic section there is a transitory dilatation of the ocular blood vessels. He attributes the fleeting nature of this response to an increased sensitivity of the denervated blood vessels to the adrenalin normally present in the blood. It is probable that the dilatation is transitory but it can hardly be due to sensitization since the law of denervation does not manifest itself for several days after severing the nerve supply.

Adler remarks further that after section of the sympathetic it might be supposed that the intraocular pressure would be increased due to the initial dilatation, yet it is almost impossible to demonstrate this in the experimental animal. In addition, Adler points out that in human beings, after the nerve has been injured, there usually results a lasting diminution in the tension together with the other commonly observed ocular signs (miosis, ptosis, and so forth). He attributes the hypotony to the loss of tone in the unstriped muscle around the globe.

Experimental procedures

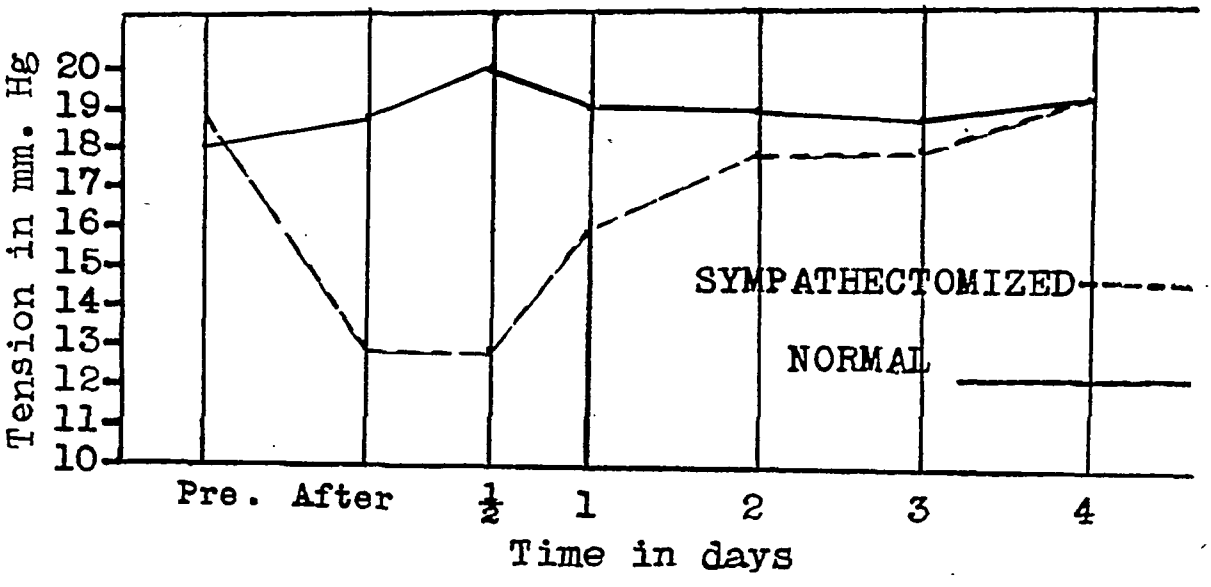
The following experiments demonstrate the intricate relationship between the sympathetic nervous system and intraocular pressure.

Experiment 1

The intraocular pressure was measured in each eye of seven normal cats. Four cats were subjected to right cervical postganglionic sympathectomy and three cats to right cervical preganglionic sympathectomy. In each case the tension was measured immediately after the operation. It was also recorded at 12-hour intervals during the first postoperative day and then at daily intervals for the next three days. Each cat showed an immediate postoperative Horner's syndrome. In no instance was the law of denervation[15] manifest during the four postoperative days. This means that there was no exaggerated response to adrenalin, excitement, and so forth. The results are shown in Table 1 which shows that in all cases the intraocular pressure on the operated side dropped immediately postoperatively. The fall ranged from 5 to 7 mm. Hg. The average drop in tension was 6 mm. There was no significant change in the tension in the left eye (unoperated side).

However, in all cases there was a rise in pressure back to the preoperative level. In almost all cases the return to normal was completed by the second postoperative day.

TABLE 1



EFFECT OF RIGHT CERVICAL SYMPATHECTOMIES ON INTRAOCULAR PRESSURE OF CATS

Cat	Operation	Preoperative Tension O.D./O.S.	Postoperative Tension					
			Immediate	Days ½	1	2	3	4
24	Postgang.	20/18	15/20	14/20	17/20	20/20	20/20	19/20
25	Postgang.	18/18	11/20	12/20	15/20	15/20	17/17	17/17
26	Postgang.	17/17	12/18	12/20	16/18	18/18	17/17	18/19
27	Postgang.	20/20	13/20	15/20	15/18	20/20	20/20	20/20
28	Pregang.	18/17	11/18	12/18	16/17	17/17	18/18	18/18
29	Pregang.	19/18	14/18	14/19	17/19	19/19	18/19	19/19
31	Pregang.	19/19	13/20	15/20	14/22	18/20	18/19	20/19

During the subsequent two days there was no variation. Graph 1 is a composite record of these results.

EXPERIMENT 2

Seven cats, which had been subjected to right cervical sympathectomy 2 to 4 months before the present experiment, were used. Four of the cats had postganglionic sections and the other three had preganglionic sections. In every case a Horner's syndrome was readily apparent. There was no regeneration in any of the cats, since the iris of the postganglionic sympathectomized animals still showed an exaggerated response to excitement while the preganglionic sympathectomized cats showed a less marked, but exaggerated response.[16]

Graph 1 (Jaffe). A composite record of the results in Experiment 1.

TABLE 2

INTRAOCULAR PRESSURE IN CATS TWO TO FOUR MONTHS AFTER SYMPATHECTOMIES

Cat	Operation	Tension O.D./O.S.
20	Pregang.	20/18
15	Pregang.	20/18
21	Pregang.	20/20
16	Postgang.	18/20
18	Postgang.	15/20
22	Postgang.	18/20
9	Postgang.	16/20

Intraocular pressure was measured in both eyes of each of the seven cats. The results are shown in Table 2.

It is seen that the cats which had a preganglionic sympathectomy showed a normal or a slightly increased tension on the operated side; whereas, those subjected to a postganglionic sympathectomy exhibited a lower tension on the operated side.

EXPERIMENT 3

The seven cats used in Experiment 1 were used here. The present experiment was performed in each case more than three weeks postoperatively so that the sympathetically denervated right iris would exhibit the phenomenon of denervation—that is, extreme sensitivity to stimuli which cause adrenalin liberation.

The tension was measured in the two eyes. Then ether was administered to the animal until it passed through the excitement stage (stage II) and into plane ii of the third stage of anesthesia. The ether was discontinued and the tension was taken. It was then recorded every 15 minutes for two hours (table 3).

The results in Table 3 show that the excitement effect of ether anesthesia caused an initial rise in pressure in all animals. The tension then approached normal at the end of 15 to 30 minutes. After this time it continued to fall. This fall was completed at the

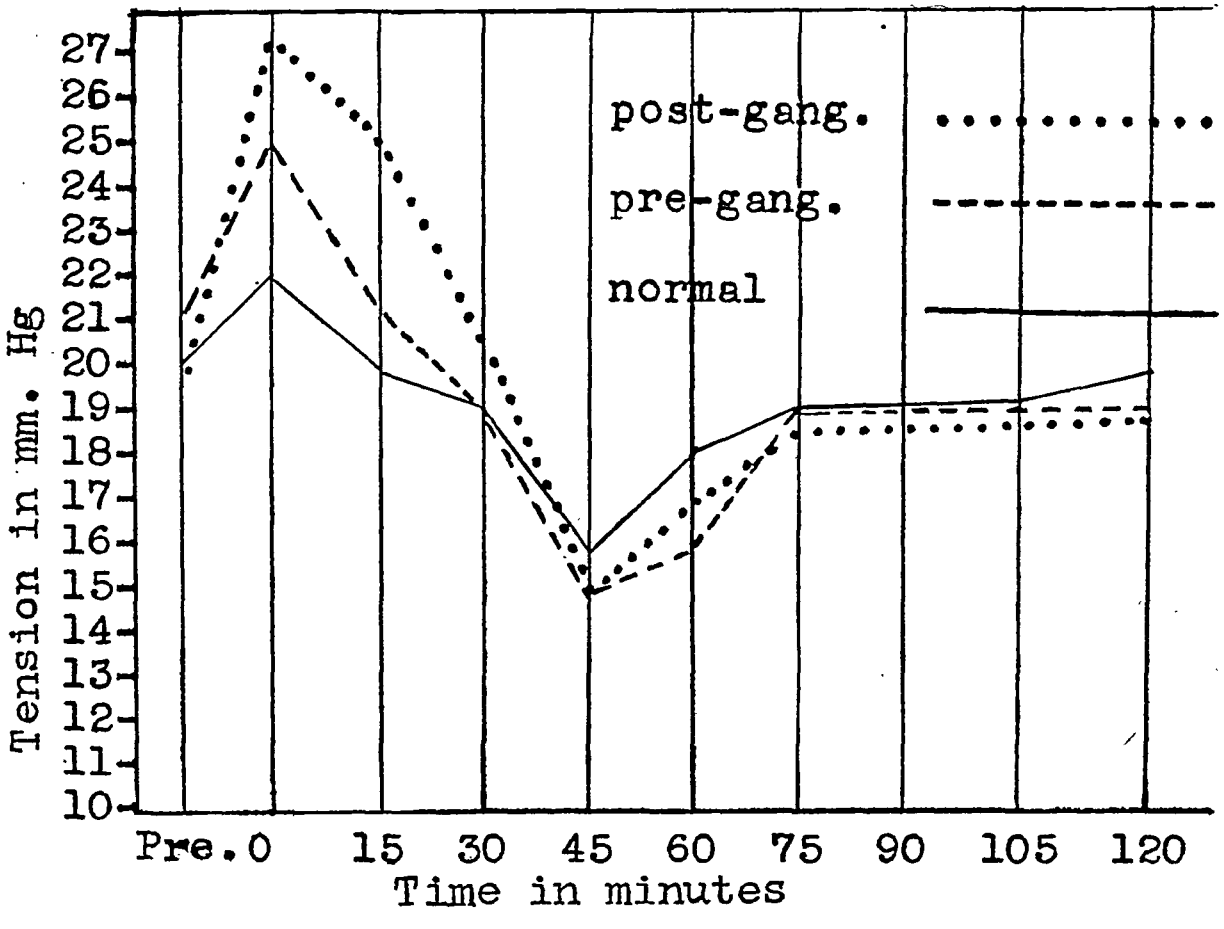


TABLE 3

INTRAOCULAR PRESSURE IN CATS AFTER ADMINISTRATION OF ETHER

27	Postgang.	18/20	26/24	24/21	21/21	17/17	16/20	18/20	20/20	18/20	18/20
28	Pregang.	18/18	28/20	26/20	20/20	16/16	18/20	20/20	20/18	20/18	20/20
29	Pregang.	20/20	26/24	24/18	18/18	14/16	18/18	20/20	18/20	20/20	20/20
31	Pregang.	18/18	26/21	24/21	20/20	14/14	16/18	18/20	18/20	20/20	20/20

end of one hour when the tension was essentially the same as that recorded before the commencement of ether administration. The second hour (60′ to 120′) showed no variations. The normal eye showed the same response; namely, initial rise with subsequent fall in tension, but to a less exaggerated extent (graph 2).

However, the type of sympathectomy is important after the law of denervation has manifested itself (two weeks or more after the operation), as shown in Experiment 2. The effector cells in the walls of the blood vessels show a more marked sensitivity to adrenalin in the case of a postganglionic than a preganglionic sympathectomy. This may

Graph 2 (Jaffe). A composite record of the results in Experiment 3.

COMMENT

The drop in pressure following cervical sympathectomy is not permanent. It lasts less than two days. It seems likely that this fall is due to paralysis of the unstriped musculature of the lids, globe, and orbit. The secondary return to normal may be the result of the accompanying vasodilatation caused by the elimination of the sympathetic tonus. There is no difference in the drop observed with preganglionic and postganglionic sympathectomies since both cause a complete removal of sympathetic tonus.

explain why the tension is lower after a postganglionic sympathectomy, since vasoconstriction results when the sensitized effector cells are exposed to the normal adrenalin level. The normal values seen after preganglionic sympathectomy are certainly due to a lack of sensitization of the effector cells.

In Experiment 3, ether, which is sympathomimetic,[16] was given to each animal. Excitement caused both sympathetic nervous system stimulation and adrenalin secretion. The initial rise in pressure of the denervated as well as the normal eye is due mainly to

elevation of the general blood pressure with passive rise in the pressure within the ocular arterioles. Contraction of the smooth musculature also contributes to this initial rise.

The rise is considerably greater with the postganglionic than the preganglionic sympathectomized animals in accordance with the law of denervation. Sensitivity of denervated autonomic structures is twice as great if a postganglionic section rather than a preganglionic section is performed.[17] Sensitivity of the effector cells in the smooth musculature of the lids, globe, and orbit cause this effect. There is also an appreciable amount of sensitization after a preganglionic sympathectomy so that the increase in tension here is greater than in the normal eyes. Also since vasoconstriction is not effective at first in the ocular arterioles and since the sympathetic tonus has been removed, the passive rise in the sympathectomized eye is greater than in the normal eye.

However, after several minutes the tension begins to fall precipitously. This is due to the onset of effective vasoconstriction of the arterioles within the eye. The latter are now able to present an adequate barrier to the induced generalized hypertension. As expected, the normal eyes do not respond as markedly as the sympathectomized eyes. The fall is greatest with the postganglionic sympathectomized eyes since the vasoconstriction is most effective. The preganglionic eyes also exhibit some sensitivity (about 50 percent) so that the fall is greater than in the normal eyes. Again the phenomenon of denervation forms the basis of these results.

As the increased adrenalin level induced by the ether excitement begins to fade, the vasoconstriction wears off and the tension returns to normal. It has been shown that the amount of adrenalin liberated during the excitement stage of ether anesthesia requires about one hour to be metabolized.[16] After slightly more than one hour, the tension in all eyes is about the same as it was before the experiment. This corresponds to the return of the adrenalin level to normal with subsequent release of the vasoconstriction. There are no changes in tension during the second hour of the experiment.

It is clearly shown that at least one of the factors associated with changes in the intraocular pressure is the sympathetic nervous system. Animal experimentation is not perfectly comparable to human experimentation due to differences in the anatomic structures concerned with the maintenance of normal tension. Nevertheless, sympathetic elements are important. However, before its role in glaucoma can be accurately estimated, considerable human experimentation will be necessary.

Summary

Section of the cervical sympathetic nerves in a cat causes a drop of from 5 to 7 mm. Hg in intraocular pressure. This fall is maintained for at least two days after which the pressure returns to normal.

After several weeks, animals previously exposed to a postganglionic sympathectomy will show a decreased tension; whereas, those exposed to a preganglionic sympathectomy will show a normal or slightly increased tension.

Excitement induced by ether causes an initial rise in intraocular pressure in all animals. The rise is greater in a postganglionic than in a preganglionic sympathectomized eye. The rise in the latter is greater than in the normal eye. The increase lasts about 15 to 30 minutes. After this time, there is a fall below normal and then a return to normal tension.

The underlying factors concerned with these changes are discussed.

The sympathetic nervous system is intimately concerned with the maintenance of intraocular pressure and only after much more experimentation will we be able to determine its exact role in glaucoma.

SULFATHIAZOLE SENSITIVITY: WITH A REVIEW OF THE LITERATURE

ARNOLD A. ALBRIGHT, COL. (MC),* AND
EDWARD L. SERETAN, MAJ. (MC)†
Battle Creek, Michigan

Sulfathiazole sensitivity in its minor manifestations is well known and not infrequently encountered. However, extremely severe reactions simulating Arthus's phenomenon may occur, as indicated by a recent case at Percy Jones General Hospital.

CASE REPORT

History. A former infantry lieutenant, aged 32 years, sustained a grenade wound in action with the Japanese on March 24, 1945. Fragments penetrated his shoulders, right arm, back, left leg, and right eye. Immediately after injury, vision in his right eye was reduced to light perception.

All wounds, except those of the eye, were debrided and sulfanilamide powder was introduced. An undetermined number of fragments were removed from the right orbit on Leyte Island in April, 1945. Another fragment was removed in October, 1945, at O'Reilly General Hospital. Vision improved gradually. However, several episodes of sharp pain in both eyes and frequent frontal headaches, relieved by aspirin, remained as his chief complaints. Discharged on a limited-duty status, he was recalled for reëvaluation and was admitted to Percy Jones General Hospital on January 14, 1947.

Physical examination revealed numerous, well-healed scars on the back, both shoulders, right arm, and left leg.

Eye examination. Vision was: O.D., 20/50, J6, correctible under cycloplegic with a +2.0D. sph. ⌒ +0.75D. cyl. ax. 105° to 20/30+2, J2. O.S., 20/20, J1, correctible to 20/15, with a +1.25D. sph. ⌒ +0.5D. cyl. ax. 105°. External examination was not remarkable.

Slitlamp study of the right eye revealed pigment granules in a fluid vitreous. Ophthalmoscopic examination showed a large area of healed traumatic chorioretinitis in the superior nasal quadrant near the periphery.

* Chief of EENT Section, Percy Jones General Hospital.
† Resident in Ophthalmology, Percy Jones General Hospital.

This was circumscribed by pigment. The left eye was normal.

X-ray examination with Sweet localization revealed a foreign body, 1 by 2 by 1 mm. in size, lying 7 mm. above the horizontal plane of the cornea, 9.5 mm. to the nasal side of the vertical plane of the cornea, and 15 mm. back of the center of the cornea, in or near the sclera of the right eye. The Berman locator confirmed the position of the metallic fragment, and at operation on January 24, 1947, with its help the foreign body was found in the sclera and dissected free without difficulty. A small amount (approximately 30 mg.) of 5-percent sulfathiazole in lanolin ointment was placed in the conjunctival sac and a dry dressing applied.

Reaction. Within 24 hours the patient developed a generalized urticaria, edema of the lids and conjunctiva in the right eye. Itching of the face and body became generalized and severe. A macular rash developed over the trunk and extremities. By this time the right eye was swollen almost completely shut, while the left eye began to show similar involvement. The healed scars of the arms and trunk became swollen, formed blebs which erupted, exuded serum, and finally became slightly necrotic. On the day following surgery, the temperature rose to 101.8°F., with a pulse rate of 142 per minute. Two days later both gradually subsided to normal.

Treatment consisted of repeated irrigation of both eyes immediately after the allergic manifestations were noted, and instillation of adrenalin (1:1,000) in both conjunctival sacs. Benadryl (50 mg.) was given orally every four hours. Except for some relief from itching, there was no amelioration of symptoms. The systolic blood pressure dropped to 75 mm. Hg, and was brought back to normal with adrenalin, following which patient developed auricular fibrillation, confirmed by electrocardiogram.

Course. Urticaria and edema of the eyes increased in severity until both eyes were swollen shut. Edema of the right cornea was severe enough to reduce vision to light perception.

After the administration of 9.5 gr. of quinidine sulfate in graduated doses, the heart rhythm and blood pressure became normal. The electrocardiogram was normal on January 26th. Edema and urticaria gradually subsided during the subsequent three weeks, and the patient's eyes returned to normal.

On February 24, 1947, vision with correction was: O.D., 20/30, J2; O.S., 20/20, J1. On February 28th, the patient met a board, which considered him fit for general duty.

Discussion

Many points of interest arise from this case. The necrosis of the former wound areas resembles the phenomenon described by Arthus in 1903. As he inoculated rabbits subcutaneously with repeated doses of horse serum, at different sites, it was noted that the primary site of inoculation would undergo a severe tissue reaction, becoming injected, swollen, and later undergoing necrosis. This is supposed to be peculiar to the rabbit, according to Topley and Wilson.[1] Our patient had been sensitized previously by sulfonamide therapy.

Untold thousands of wounded servicemen were treated by sprinkling their wounds with sulfonamide crystals. Of these a large number were given further sulfonamide therapy in their subsequent care. Therefore, the number of ex-servicemen sensitized to sulfonamide drugs may be high.

Review of literature

In reviewing the literature, we were struck by the paucity of detailed information concerning idiosyncrasy to any of the sulfonamide derivatives when instilled in the eye. Morrison,[2] in 1942, called attention to allergic conjunctivitis from the topical use of sodium sulfathiazole and sulfathiazole, and cited a case of severe allergic blepharoconjunctivitis.

Shaffer, Lentz, and McGuire,[3] in 1943, called attention to the fact that sulfathiazole used locally on the skin is capable of causing cutaneous sensitization, which may manifest itself as a local contact type dermatitis with or without generalized eruption; also that sensitization produced by local application may be elicited by oral administration.

Alvaro[4] reviewed the literature and listed the effects of sulfonamide compounds on the eye. He lists palpebral edema, conjunctivitis, chemosis, scleral reaction, cells in aqueous, iritis, mydriasis, cataract, edema of the retina, reduction of visual fields, retinal hemorrhages, optic neuritis, undefined blurred vision, transient ametropia, changes in accommodation, and heterophorias as the side effects. Most of those listed are as a result of sulfonamide therapy taken orally.

Alvaro[5] also states that sulfonamides are almost innocuous to the ocular tissues when applied locally, and that when local intolerance occurs, it is demonstrated by lid dermatitis and conjunctivitis, which subsides as soon as treatment is discontinued. He recommends the local use of sulfonamides because of easy penetration and tolerance.

Except for the cases cited, local intolerance is mentioned more or less casually, but there have been no cases reported similar to this one. However, various ocular reactions to peroral sulfonamide have been reported. The first report in literature of sulfonamide intoxication was made by Bucy,[6] in 1937, in which a case of optic neuritis developed.

In 1939, Rosenthal[7] noted field changes with angioscotometry, in which there was a narrowing of the vessel shadow induced by sulfanilamide. In 1940, Baker[8] reported retinal hemorrhages in a patient receiving sulfanilamide by mouth.

Bloom, Leech, and Shaw[9] report a case of temporary blindness, associated with retinal hemorrhage and sulfathiazole nephritis in a patient treated by peroral sulfathiazole for pyelitis and cystitis. Goar,[10] in 1942, reported two cases of retinal hemorrhages following ingestion of sulfathiazole. In 1942, Carlbuerg[11] reports four cases with myopia varying from 2 to 4.50D. due to lens changes. Numerous cases of transient myopia have since been reported.

Bellows,[12] in reviewing the literature, mentions optic neuritis, round hemorrhages around swollen arterioles, greenish scleral discoloration, bluish discoloration, temporary blindness, transient myopia, and field changes.

Savitsky and Weitzen[13] report a case of dysmorphopsia associated with blurring of vision in a woman receiving sulfanilamide by mouth. Laval[14] reports a case of paresis of accommodation in a 17-year-old girl after she had received 11½ gm. of sulfadiazine in five days for an upper respiratory infection.

Scott and Sorsby[15] list the following complications to sulfonamide therapy, but do not specify whether the medication was given locally or systemically: Transitory myopia, retinal hemorrhage, optic neuritis, and conjunctival reactions; for example, color changes, cyanosis, and pallor.

Fritz and Kesert[16] describe a case of acute congestive glaucoma following oral sulfathiazole for sore throat.

In a recent editorial in the *American Journal of Ophthalmology*, Cordes[17] sounds a warning against the indiscriminate use of sulfonamides and penicillin. He states that sulfathiazole, locally in even infinitesimal doses, can induce sensitivity. He also calls attention to reports in the literature of individuals, sensitized to one sulfonamide by local use, reacting to another type of sulfonamide after oral administration. Attention is also drawn to kidney damage and anemia. Cordes, with Thygeson, recommends sulfadiazine as being less toxic and less apt to produce sensitivity, and that sulfonamides should not be used longer than two months.

Sodium sulfacetimide (Albucid soluble) merits consideration, inasmuch as Benedict and Henderson[18] observed only one case in 65 sensitive to this drug.

Summary

1. A small amount of 5-percent sulfathiazole ointment was instilled in the conjunctival sac of a wounded officer previously treated with sulfanilamide. The patient underwent a severe local and generalized reaction. Findings included edema and chemosis of both eyes; generalized urticaria and itching; necrosis of wounds formerly treated with sulfonamide; and fall of blood pressure.

2. Treatment of sensitivity reaction consisted of topical adrenalin, benadryl in 50-mg. doses, and sodium-bicarbonate soaks. Edema did not subside in the right eye for three weeks.

3. A reaction similar to that described by Arthus in rabbits was seen in this case.

4. The literature reveals no similar case of sensitivity.

Conclusion

Severe sensitivity reactions may develop with the use of sulfathiazole, and probably with other sulfonamides. Therefore, a word of caution is offered, with the suggestion that a careful history be elicited in the event of contemplated local use in the eye of sulfathiazole or other sulfonamides. It would appear from the literature that sulfadiazine or sodium sulfacetimide (Albucid soluble) would be the sulfa drug of choice.

LOCAL ANESTHESIA IN OPHTHALMOLOGY*

WALTER S. ATKINSON, M.D.
Watertown, New York

The purpose of this paper is to review briefly a few local anesthetic procedures that have been found satisfactory over a period of years.

We have all observed that many operative accidents which occur during intraocular operations are due to a forcible contraction of the orbicularis, the rectus muscles, or to a quick movement of the eye, all a result of incomplete anesthesia. Therefore, it is extremely important to produce complete anesthesia, and as painlessly as possible, before beginning the operation.

While the principal aim of anesthesia is to prevent physical pain, it is also important to allay fear and apprehension which may shock the patient as severely as pain. The patient who comes to us for operation has confidence; otherwise he would not entrust his most valuable possession, sight, to us. His confidence though is easily undermined so every act and word in connection with the preparation of the patient for operation should be carefully studied. Usually the less said, the better. A thoughtless remark or trivial act may excite fear and apprehension. Then, confidence, which is so illusive, is difficult to regain.

Patients undoubtedly differ to as great an extent in their mental as they do in their physical characteristics and so should be approached as differently as one would approach the various surgical conditions encountered.

Before operation and during the preparation of the patient and the production of local anesthesia, patients are particularly apprehensive. Their sensibility to pain is greatly exaggerated so that each needle prick seems to be of increasing intensity. It is, therefore, of the greatest importance to induce anesthesia painlessly in order to retain and strengthen the patient's confidence. Any complaint of pain usually indicates the incorrect administration of the anesthetic rather than a defect in the procedure or the anesthetic agent.

Local anesthesia demands and allows deliberation and care in all of the manipulations of the surgeon, and the time during which local anesthesia is produced offers an excellent opportunity to build up the patient's confidence.

SEDATIVES

Sedatives, if used carefully, are a valuable aid and assist greatly in production of a quiet and tranquil patient. But, as we all know, the action of sedatives varies greatly with different patients. In some they increase excitability and may cause nausea and vomiting, so that it does not seem advisable to use any sedative, particularly for intraocular operations, without first ascertaining the action of the drug on the patient. Usually the patient is admitted to the hospital at least one day before the operation. On the first night in the hospital a sedative may be given which acts as a test dose. This allows the operator not only to learn the action of the drug on that patient but, if it acts in the usual manner, gives the patient a quiet, restful sleep, which is excellent preliminary preparation for the operation and may be repeated with comparative safety before operation.

Some of the barbituric acid group, such as pentobarbital sodium and phenobarbital, are popular preoperative sedatives for globe operations as they rarely cause nausea or other undesirable reactions. They also have the added value of counteracting to some extent the toxic action of the anesthetic agent.

Some patients require a larger dose than

* Presented at the Clinical Congress of the American College of Surgeons, New York City, September 9, 1947.

others. Small doses repeated until the desired effect is produced, seem more satisfactory than the routine use of a large set dose. With too much sedative the patient may be as uncoöperative as an acute alcoholic. Elderly persons often take a sedative regularly and, if so, it is advisable to prescribe the one to which they have become accustomed.

As a test dose, pentobarbital sodium (1.5 gr.) with acetyl salicylic acid (5 gr.) has been found excellent for the average adult. If there is no undesirable reaction, pentobarbital (3 gr.) with acetyl salicylic acid (5 gr.) is given one hour before the operation. Only in exceptional patients is it necessary to increase this dose.

Instillation anesthesia

Since the introduction of cocaine, chemists have produced numerous local anesthetic agents, some of which have in a large measure replaced cocaine. While cocaine is still popular, the chief objections to its use are that it dilates the pupil and may influence the intraocular pressure. Cocaine also causes desiccation of the corneal epithelium and may devitalize the cornea which tends to retard healing.

Tetracaine (pontocaine) hydrochloride, a derivative of procaine, is one of the more popular local anesthetic agents used for instillation anesthesia. The chief advantages of tetracaine are: it smarts very little when it is instilled in the eye; its action is rapid and prolonged; the pupil is not dilated; the intraocular pressure is not influenced, nor is the accommodation affected. Tetracaine does not cause desiccation of the corneal epithelium nor does it devitalize the cornea.

All local anesthetic agents probably delay healing of the corneal epithelium to some extent. Gundersen and Liebman[1] found 0.5-percent tetracaine hydrochloride to be the least toxic to the regenerating epithelium. Smelser and Ozanics[2] conducted experiments which confirmed the recognized belief that frequent topical application of anesthetics inhibited cell migration and mitosis. Therefore, prolonged use of any local anesthetic is contraindicated.

Patients are rarely sensitive to tetracaine but, as with atropine and many other drugs used in the eye, a conjunctivitis and dermatitis of the lids may be caused so this possibility should be kept in mind. Larocaine, metacaine, nupercaine, and other local anesthetic agents may compare favorably with tetracaine. However, the use of tetracaine routinely for 15 years has convinced me that it is an excellent local anesthetic agent. Other anesthetics have been tried and compared with tetracaine clinically but none were found to be superior. The usual strength of tetracaine hydrochloride used for instillation anesthesia is 0.5 percent, although some surgeons prefer a 1-percent solution.

Infiltration and block anesthesia

Although there have been many anesthetic agents produced for infiltration and block anesthesia, procaine hydrochloride (novocaine) is still generally conceded to be the anesthetic of choice for injection.

The strength of the procaine hydrochloride used for the injections to be described later is 2 percent with epinephrine hydrochloride (1:1,000) 1 mm. in 5 cc. The amount of epinephrine is increased for the retrobulbar injection when hypotony is desired and to retard the absorption.

Braun[3] states that a 0.4-percent solution of potassium sulphate added to the solution of procaine hydrochloride greatly increases its anesthetic properties and in this concentration produces neither local nor general injury.

Instruments

Syringes. The Luer-Lok syringes, 2 and 5 cc. (fig. 1), have been found excellent for injections around the eye. They have a lock which prevents the needle from coming off during the injection; they are light and are not damaged if placed in a boiling sterilizer.

Needles. Three sizes of needles are desirable: a 27-gauge needle, 12.5 mm. in length,

for subconjunctival injections, intradermal wheals and small subcutaneous injections; a 25-gauge needle, 2 cm. in length, for deeper subcutaneous injections, production of akinesia, and so forth; and a 22-gauge needle, 3.5 cm. long, for still deeper injections, such as retrobulbar injection within the muscular cone and to block the lids. If the point of the needle used for retrobulbar injections is ground down so that the point is rounded, it is less likely to injure the tissues or pierce a vessel (fig. 2).

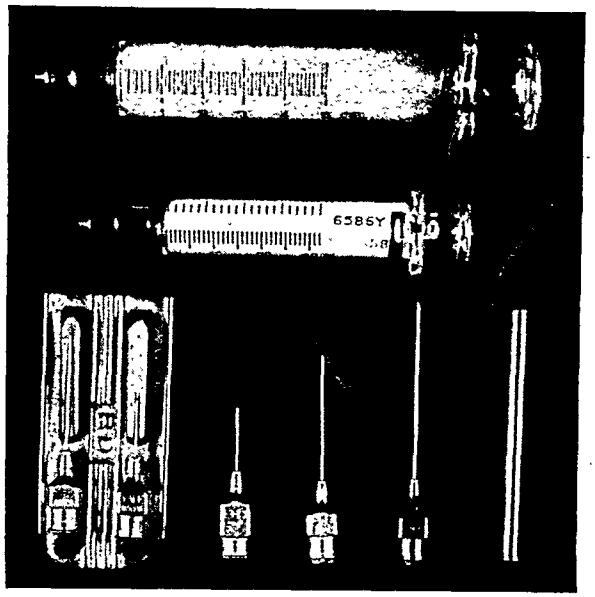

Fig. 1 (Atkinson). Luer-Lok syringes and needles.

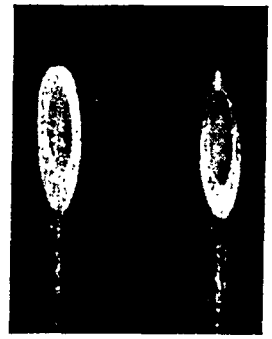

Fig. 2 (Atkinson). Rounded needle point and the regular sharp-pointed needle.

Akinesia

The desirability of having a temporary paralysis of the orbicularis muscle for intraocular operations, particularly extraction of cataract, is so generally conceded that comment is unnecessary. The method used to obtain paralysis of the orbicularis seems of less importance than to be certain that it is obtained before the operation is begun. Of the various modifications of the van Lint[4] method of producing paralysis of the orbicularis the simplest and most satisfactory is the one proposed by O'Brien.[5]

As is well known, in the van Lint method the needle is introduced at the temporal margin of the orbit (fig. 3) and an injection is made downward and nasally close to the bone to block the branches of the facial nerve which supply the lower lid. The needle is then partially withdrawn until the point is just beneath the skin and the needle is then redirected and the injection made upward to block the branches which supply the upper lid.

By the O'Brien method the temporofacial division of the facial nerve is blocked just anterior to the tragus of the ear (fig. 3). If the patient is asked to open his mouth, the condyloid process can be easily felt. The needle is then introduced until the condyloid process is just felt with the needle and about 3 cc. of the anesthetic solution is injected. If the periosteum is pricked with the needle unnecessary pain is caused.

Fig. 3 (Atkinson). The dotted line indicates the site of the van Lint injection, and the needle marks the site of the O'Brien injection, to produce temporary paralysis of the orbicularis muscle.

Deep massage with firm pressure over the site of the injection will diffuse the anesthetic solution and produce more rapid and complete paralysis of the orbicularis muscle. The course of the nerve varies considerably, so that paralysis is not always obtained with the first injection. If, after several minutes, the muscle is still active, another injection should be given and the site of the injection changed to correspond to the more common variations in the course of the nerve. Klein[6] found on dissection that the nerve more often crossed the ramus of the mandible lower than shown in most textbooks. In any event, the object of the injection should be accomplished before proceeding with the operation. A simple test to tell whether or not complete paralysis of the orbicularis has been obtained is to hold the lids open and ask the patient to close the eye. The slightest action of the orbicularis can, in this way, be felt.

One now rarely hears the criticism that the lids may come open under the dressing and so damage the eye. This does not occur, in normal cases, if the dressing is applied carefully. When the eyes are prominent and the lids do not close well, a suture to hold them closed may be easily introduced. The reason the O'Brien method is preferred is because one small injection to block the temporofacial nerve before it branches seems simpler and more efficient than to block its many branches at the orbital margin.

While the principal indication for akinesia is to prevent a "squeeze" or forcible contraction of the orbicularis in globe operations, it is also of value in other operations to obtain a larger operative field when the lids are not held open well, such as operations for detachment of the retina and muscle operations when done with local anesthesia.

When more prolonged paralysis of the orbicularis is indicated, as with patients who have a tic, with spasmodic contractions not only of the orbicularis but of other facial muscles, alcohol may be added to the solution to be injected as suggested by de Saint-Martin.[7]

The following solution, which contains 25-percent alcohol, causes little pain when injected, and the paresis lasts 7 to 10 days, sometimes longer:

Isotonic solution of sodium chloride U.S.P. ..8 cc.
Procaine hydrochloride .....0.2 gm.
Absolute alcohol .....2.00 cc.

Less pain will be experienced if 1.5 cc. of procaine hydrochloride (2 percent) is first injected, after which the syringe may be removed and the needle left in place. Beginning paresis of the orbicularis muscle indicates that the needle is in the proper position. The syringe containing the alcohol is then attached to the needle and 1.5 cc. are injected.

Retrobulbar injection within the muscular cone

In the preparation of the patient for an intraocular operation, such as a cataract extraction, let us assume that the patient has had a sedative and an anesthetic solution instilled in the eye to produce superficial anesthesia of the anterior segment and anesthesia of the conjunctiva. A retrobulbar injection within the muscular cone, or cone injection, is now given to produce more complete anesthesia.

Technique

An intradermal wheal is first made to avoid causing unnecessary pain whenever the skin is to be pierced. To some this may seem unimportant but since the aim of anesthesia is to eliminate pain we should certainly try to avoid causing pain during the production of anesthesia. Braun[8] emphasizes this and reminds us that the skin, with its innumerable nerve endings, is probably the most sensitive tissue in the body.

For the cone injection, the wheal is made just below the inferior temporal margin of the orbit (figs. 4, 5, 6) using a 27-gauge needle with the bevel toward or flat against

the skin. The 22-gauge needle, 3.5 cm. in length, is then introduced through the wheal, the skin is moved upward with the needle until the point just clears the inferior orbital margin. About 0.5 cc. of the anesthetic solution is now injected so that little pain will be experienced when the orbital septum is pierced and it can be pierced more

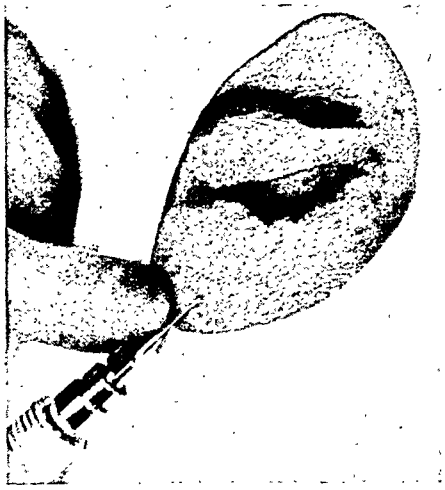

Fig. 4 (Atkinson). Intradermal wheal.

easily close to its attachment to the orbital margin.

A pause of a few moments allows the anesthetic to work during which time the patient is directed to look upward and away from the site of the injection; in this instance up and to the left for injection of the right cone. The needle is then directed upward and inward, midway between the lateral and the inferior rectus muscles. It is then advanced toward the apex of the orbit for a distance of 2.5 to 3.5 cm., the distance depending upon the size of the orbit. When the needle has reached the proper depth, one should aspirate before injecting the anesthetic solution in order to determine whether or not the needle has entered a vessel. However, in this location this is practically impossible unless there is an anomalous vessel, since here the vessels are normally smaller than the needle and are freely movable.

Again the importance of using a large, 22 gauge, needle not longer than 3.5 cm. with a rounded point should be emphasized. If a 4.5- or 5-cm. needle is used and the point carried to the apex of the orbit, obviously

Fig. 5 (Atkinson). Retrobulbar injection within the muscular cone.

a vessel or the optic nerve might easily be pierced, because here the vessels converge to reach their bony exits and are fixed.

From 1 to 1.5 cc. of the procaine epinephrine solution is slowly injected, care being taken not to produce undue proptosis by too large an injection. For the majority of operations on the globe, 1 cc. is sufficient, but for operations on the muscles and for enucleation, 3 cc. or more may be injected, as the proptosis does no harm and, for inflamed

Fig. 6 (Atkinson). Skull showing position of needle for retrobulbar injection.

and painful eyes, more procaine is desirable.

Gentle massage with a rotary motion of the globe causes the procaine solution to become more thoroughly diffused within the muscular cone. In this way more complete and rapid anesthesia is produced. Anesthesia of the muscles is not obtained as rapidly as anesthesia of the globe; so for enucleation and operations in which there is considerable traction on the muscles it is advisable to wait 5 or 10 minutes before beginning the operation.

Blocking of sensory nerves

By means of the injection within the muscular cone, all of the sensory nerves to the eyeball are blocked, and complete anesthesia of the globe is obtained regardless of how inflamed or painful the eye may be. Pressure on the inflamed eye, which before the injection caused severe pain, is not noticed now. The rectus muscles, except the superior rectus, are also rendered practically insensitive to traction.

The injection within the muscular cone also causes paresis of the rectus muscles, except the superior rectus, so that the patient cannot look down easily. Therefore, for such operations as extraction of cataract, it is advisable to use a suture under the superior rectus muscle (bridle suture). With the rectus muscles inactive, little traction is required to hold the eye in the desired position. Also, better fixation of the globe is thus obtained. With paresis of the rectus muscles the so-called squeeze, with loss of vitreous, caused by their contraction is less likely to occur.

The superior rectus muscle usually remains active and may be sensitive to traction. For prevention of pain when this muscle is picked up for the introduction of a bridle suture or for an operation in which there is traction on the muscle, additional anesthesia is necessary. This may be accomplished by an injection of 0.5 cc. of the anesthetic solution along the superior rectus muscle. With the superior rectus muscle active and with paresis of the other extrinsic muscles, there is torsion of the globe, with rotation toward the nose. The torsion is increased when a suture is used under the superior rectus muscle. Therefore, if an iridectomy is to be performed, it should be done from 10 to 15 degrees to the nasal side, so that the coloboma will be at axis 90° when the muscles again function normally. While this is of no particular importance from a visual standpoint, a coloboma looks better in the vertical meridian.

Subconjunctival injections

When the eye is red and inflamed, as in cases of acute glaucoma, a subconjunctival injection should also be given, since the inflamed conjunctiva is not well anesthetized by topical application and only the conjunctiva immediately adjacent to the limbus for a distance of about 3 or 4 mm. is rendered insensitive by an injection within the muscular cone. This is because the nerve supply is from the ciliary nerves, which are within the cone.

The rest of the conjunctiva is innervated by the supraorbital, supratrochlear, infratrochlear, infraorbital, and lacrimal nerves, all of which are outside the muscular cone and are seldom reached by the anesthetic injected within the cone. When the eye is inflamed, less pain is caused if the subconjunctival injection is given after the retrobulbar injection.

For the subconjunctival injection the needle may be introduced through the insensitive conjunctiva directly surrounding the cornea and, if succeeding injections are made through blebs produced by the anesthetic, little pain will be experienced. In this way, pain due to the use of the fixation forceps and to suturing of the conjunctiva is avoided in eyes that are inflamed and painful. A 27-gauge needle is used and slid gently over the conjunctiva until a fold appears in front of the point; the syringe is then rotated, which produces a boring effect. In this way even a dull needle passes easily

through the conjunctiva without the use of forceps. If the bevel of the needle is toward the globe, one is less likely to prick the sclera and cause bleeding.

With such complete anesthesia of the globe, the eye being practically immobile together with paralysis of the orbicularis muscle, operations on the globe can be performed with the same deliberate precision that one can use when operating on the cadaver.

Action of anesthetic

If the patient looks upward and away from the site of the injection, access to the muscular cone is easier. The extension of the fascial sheath of the muscles which closes the spaces between the rectus muscles for a little distance back of the globe is in this way moved forward and upward, out of the way, so that the needle does not strike it, as is shown diagrammatically in Figure 7. If the needle does strike the sheath, pain is caused. The sheath is also somewhat tough, and the needle does not penetrate it easily, with the result that the globe rotates, which to some extent interferes with the introduction of the needle and the equilibrium of the patient.

The injection is made through the skin at the inferior temporal margin of the orbit rather than through the conjunctiva because it is less painful and allows a better angle of approach to the muscular cone. Procaine injected within the muscular cone is apparently held within the cone, since the nerves outside the muscular cone are rarely affected and injections outside of the cone do not reach the nerves that traverse the cone.

How is the solution of procaine held within the muscular cone, since there is no demonstrable fascia between the rectus muscles posterior to the globe, as they converge to their attachment at the apex of the orbit?

Anteriorly, the escape of fluid is prevented by the globe, surrounded by Tenon's capsule, and by the adjacent margins of the sheaths of the four rectus muscles, which are continuous with one another, with a wide sweep between them. In this manner, an intramuscular membrane is formed which, according to Whitnall,[9] exists for a short distance behind the globe. Beyond this the muscles converge to their attachment through the annulus of Zinn, at the apex of the orbit, and

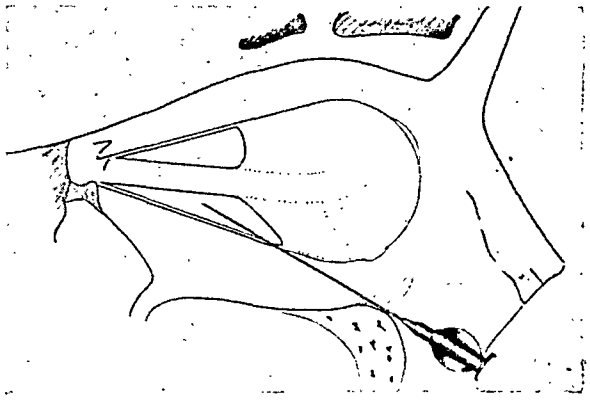

Fig. 7 (Atkinson). Diagrammatic sketch showing the eye turned up and away from the site of the injection, so that the fascial extension is moved forward and upward out of the way.

their margins come closer together, so that comparatively little space is left between them. In this location the escape of the procaine solution is probably prevented, or at least retarded, by the closely packed layer of fat, with its connective-tissue reticulum.

According to Whitnall,[10] the orbital fat which fills the entire space in the orbit not occupied by other structures varies in consistency in different regions. Within the muscular cone the fat has the appearance of large and loosely connected lobules, broken up by the passage of the nerves and vessels. Outside the muscular cone the fat is more firmly packed and contains a quantity of connective tissue, which is closely attached to the muscular sheaths. No doubt this fat and connective tissue serve as a sufficient barrier so that the anesthetic solution is held within the cone, with production of anesthesia or blocking of the nerves that traverse it—the nasociliary nerve, the long and short ciliary nerves, the ciliary ganglion, the optic

nerve, and all the motor cranial nerves except the trochlear, or fourth. The importance of injecting the anesthetic solution into the cone is obvious if complete anesthesia of the globe is to be obtained.

Decrease in intraocular pressure

A decrease in the intraocular pressure occurs after injection within the cone. If the amount of epinephrine hydrochloride (1:1,000) is increased to 3 or more drops to 5 cc. of the anesthetic solution, the decrease in the intraocular pressure is greater, and a decrease of as much as 20 to 30 mm. Hg may be noted in cases of acute glaucoma with high intraocular pressure.

After the injection within the cone, there is often noticeable deepening of the anterior chamber, particularly when the amount of epinephrine hydrochloride is increased. This indicates a decrease in the fluid contents of the eye posterior to the diaphragm. The incision for cataract extraction is thus made easier in cases in which the chamber has been shallow. Also, with lowering of the pressure behind the lens, the anterior capsule seems to become relaxed. In some cases the capsule of the lens, which prior to operation appears to be too tight to be grasped with smooth forceps, is found to be loose enough after an injection within the cone so that a good bite of the capsule can be obtained with the forceps.

With some methods of intracapsular extraction of cataract a decrease in the intraocular pressure seems to be an advantage, as it lessens the possibility of prolapse of the vitreous. This is also true in the removal of intraocular foreign bodies by the scleral route. In extraction with capsulotomy it is often more difficult to express the lens when the pressure is decreased. With deeply set eyes the operation is somewhat facilitated if the eye is slightly proptosed. With lowered intraocular pressure the iris may not prolapse well in corneoscleral trephinations, an incident which may be embarrassing.

The decrease in the intraocular pressure following the injection of procaine and epinephrine within the cone may be accounted for by the constricting action of the epinephrine on the arteries entering the globe, an effect which would tend to decrease the amount of blood entering the globe but would not impede its exit through the venae vorticosae, since the solution does not reach them, located as they are in the episcleral space. The free anastomosis of the venae vorticosae and other orbital veins with the facial vein allows free exit of the blood.

Indications for cone injection

The indications for a cone injection are: globe operations, muscle operations, enucleation, evisceration, and, as suggested by Icaza,[11] in cases of acute glaucoma for the immediate relief of pain. In acute glaucoma the intraocular pressure is also lowered rapidly, particularly if the amount of epinephrine is increased. The pupil is then more easily contracted and the pressure controlled with a miotic. However, Scheie,[12] has found that physostigmine (eserine) has no effect on the pupil for 1 to 3 hours following a cone injection of procaine hydrochloride while pilocarpine promptly constricts the pupil.

Operations on the lacrimal sac

For extirpation of the lacrimal sac quite satisfactory anesthesia may be obtained by infiltration anesthesia around the sac and the injection of anesthetic solution into the sac. However, some pain will usually be experienced when the sac is excised from the nasolacrimal duct, or when the duct is curetted, because the anterior superior alveolar nerve which supplies these parts is not reached. To block the anterior superior alveolar nerve, an injection proximal to where it branches off the infraorbital nerve within the infraorbital canal is indicated because it passes through osseous canals to supply the lower part of the lacrimal sac and the nasal duct and so is not reached by an injection around the sac.

More complete anesthesia for operations on the lacrimal sac may be obtained if the nasociliary nerve is blocked at the anterior

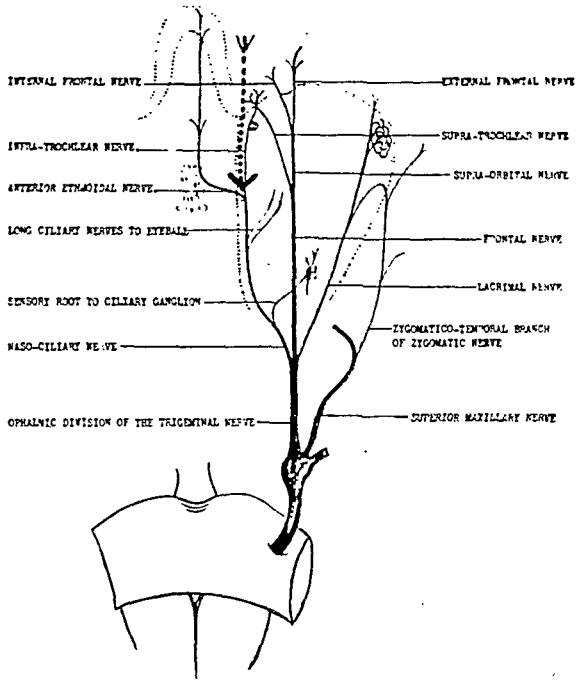

Fig. 8 (Atkinson). Diagram showing the distribution of branches of the ophthalmic division of the trigeminal nerve (after Whitnall). Arrow indicates site of injection for block of nasociliary nerve.

Fig. 9 (Atkinson). Skull showing needle in position to block the nasociliary nerve.

ethmoid foramen so that both the anterior ethmoidal and infratrochlear nerves are blocked (fig. 8).

For this injection, the 3.5-cm. needle is

Fig. 10 (Atkinson). Injection to block the nasociliary nerve.

introduced a little above and to the nasal side of the trochlea (figs. 9, 10). The needle is kept close to the superior nasal wall and at a depth of 3 cm., and 2 or 3 cc. of a 2-percent solution of procaine hydrochloride with epinephrine hydrochloride is injected. On withdrawing the needle another injection is advisable along the orbital margin in the vicinity of the supraorbital notch anterior to the orbital septum but close to the periosteum. Occasionally the angular vein (fig. 11) is pierced, but if the anesthetic solution is not injected into the vein no harm is done,

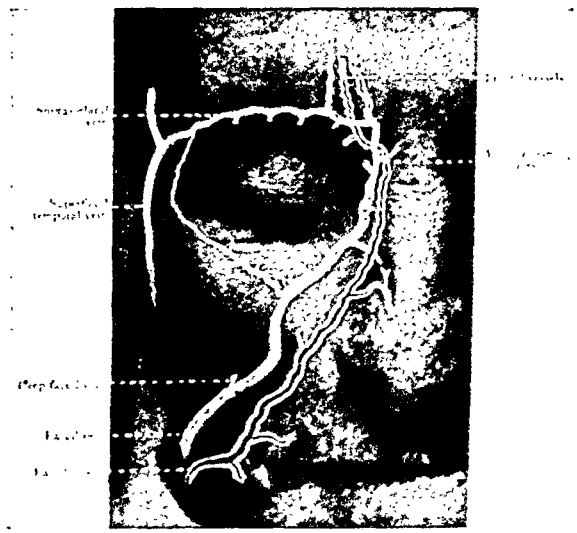

Fig. 11 (Atkinson). Vessels to avoid in block of nasociliary nerve (after Whitnall).

Fig. 12 (Atkinson). Skull showing position of the needle for injection into the infraorbital canal to block the infraorbital and the anterosuperior alveolar nerve.

although the resulting ecchymosis is annoying.

The block of the infraorbital nerve proximal to the anterior superior alveolar nerve may be made in the infraorbital canal or inferior orbital fissure.

To inject the infraorbital canal, the needle

Fig. 13 (Atkinson). Injection into the infraorbital canal.

is introduced 1 cm. from the middle of the ala of the nose and carried almost to the bone. It is then directed upward and temporally at an angle of 20 degrees (figs. 12, 13) and kept in close contact with the bone, injecting the procaine solution as it advances.

The foramen is found more easily if the index finger of the other hand is placed over the foramen, as suggested by Labat,[13] indicating the location of the foramen and the axis of the infraorbital canal. Usually a small depression is felt at the opening of the canal, 0.5 to 1 cm. below the inferior orbital margin, about in line with the supraorbital

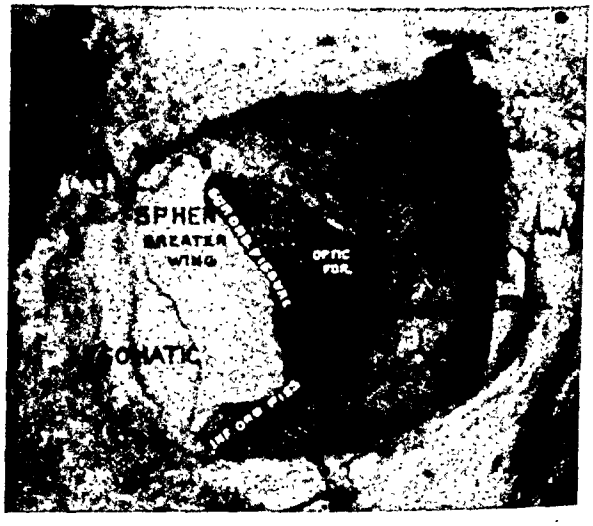

Fig. 14 (Atkinson). Orbit showing inferior orbital fissure and infraorbital canal (after Whitnall).

notch which helps to locate it. The needle is introduced along the canal 0.5 cm. to 1 cm. so that the injection will be proximal to the branch of the anterior superior alveolar nerve.

If the foramen is not found or is not present, as is occasionally the case, the block can be made in the inferior orbital fissure (fig. 14). To reach the fissure, the 22-gauge, 3.5-cm. needle is introduced as for a cone injection. As soon as the point of the needle passes through the orbital septum it is directed toward the floor of the orbit in the same plane as for the cone injection (fig. 15, 16). The point of the needle is moved along the orbital floor from 1.5 to 2.5 cm. until the fissure is felt; it is then introduced 1 cm., and 1 to 2 cc. of the procaine solution is injected.

Infiltration over the site of the sac decreases bleeding but is not necessary for anesthesia. For the operation of dacryocystorhinostomy, in addition to block of the nasociliary and the infraorbital nerves, topical anesthesia of the nasal mucous membrane should be obtained by the use of a nasal pack.

Fig. 15 (Atkinson). Skull showing position of needle for injection into inferior orbital fissure for block of the infraorbital nerve.

Fig. 16 (Atkinson). Injecting the inferior orbital fissure to block the infraorbital nerve.

FIELD BLOCK FOR ANESTHESIA OF THE LIDS

Since there are so much overlapping and variation in the sensory nerve supply of the lids (fig. 17), it is simpler in operations in-

Fig. 17 (Atkinson). Right eye: The sensory nerves are indicated by solid lines (after Whitnall). Left eye: Injections for block of lids indicated by arrows.

volving a considerable area of the lids to produce a field block rather than to try to block the individual nerves.

Injection, using the 3.5-cm. needle, is made at the center of the orbital margin as shown (left eye) in Figure 17, above or below, the position depending on which lid is to be blocked. The point of the needle should follow the orbital margin closely but should not penetrate the orbital septum. A 2-percent solution of procaine hydrochloride with epinephrine hydrochloride (1:1,000) is injected slowly as the needle advances. In order to inject the anesthetic all along the margin and to infiltrate well the tissue around the nerves that emerge from the orbit, it is necessary to withdraw the needle a little and redirect it several times. The injection should not be made just under the skin, but should be close to the periosteum. An extra 0.5 cc. of the anesthetic solution should be injected deep in the vicinity of the supraorbital notch.

After the anesthetic solution has been injected along one half the superior or the in-

ferior orbital margin, the location depending on which lid is to be blocked, the needle is partially withdrawn; it is then redirected and the solution injected along the other half of the orbital margin. Each injection should be carried beyond the line of the palpebral fissure.

For removal of small tumors of the lids, such as papillomas, infiltration at the site of the tumor is usually sufficient and is the simplest method. It also decreases the bleeding. For chalazion and operations involving the margin of the lid which, owing to its rich nerve supply, is extremely sensitive, instillation anesthesia and infiltration at the site of the chalazion are often not sufficient to make the operation painless. However, instillation anesthesia and an injection of 1 cc. of the anesthetic solution through the conjunctiva of the cul-de-sac or through the skin to reach the same location in the sector of the lid where the chalazion is located, will more frequently produce complete anesthesia.

Conclusion

Most eye operations may be safely performed without pain with local anesthesia.

ECZEMATOUS KERATITIS AND ARIBOFLAVINOSIS*

H. J. STERN, M.D.
New York
AND
J. LANDAU, M.D.
Jerusalem, Palestine

Eczematous (phlyctenular or scrofulous) keratitis is most commonly regarded as an allergic condition. It occurs mainly in children with so-called scrofulous diathesis. Enlarged tonsils and adenoid vegetations are very frequently present, and the submandibular glands are often found to be enlarged. The disease is characterized by diffuse infiltration of the conjunctiva and the corneal epithelium, with marked hyperemia, and multiple lymphocytic nodules of varying size on the bulbar conjunctiva or at the limbus which may break down and become infected. The condition is often accompanied by intense pain and blepharospasm. Infiltration of the limbus leads to the development of superficial vessels at the periphery of the cornea, a condition which is called eczematous, scrofulous, or phylyctenular pannus. It is common to find eczematous lesions around the nose and the mouth.

The hypersensitivity of the conjunctival and corneal tissues is supposed to originate from a hidden, usually clinically healed, tuberculous lesion. However, it need not necessarily have been provoked by the tuberculous antigen, but may possibly have been induced by other bacterial toxins (hetero-allergy).

Treatment consists of the administration of yellow oxide of mercury, calomel, dionin or atropine, the local application of heat, general improvement of the diet and living conditions, change of climate, ultraviolet irradiation, or cod-liver oil. However, the treatment, which is very tedious, may prove disappointing in many cases, and frequent relapses are the rule.

In recent years several authors have claimed that riboflavin exerts a beneficial effect on a number of corneal diseases of different etiologies, among them eczematous keratitis.[1, 2] A certain clinical resemblance between eczematous keratitis and the acute manifestations of ariboflavinosis has induced us systematically to examine the efficacy of riboflavin in this disease.

CASE REPORTS

Case 1. M. M., a girl aged 10 years, with typical signs of scrofulous diathesis, had been treated at our clinic for phlyctenular keratitis four times in the course of the past four years. On every occasion treatment had to be continued for many weeks before the condition cleared up.

This time she had been under treatment for four weeks (atropine, yellow oxide of mercury, sulphathiazole, and cod-liver oil) when it was decided to attempt riboflavin therapy.

At this stage the patient's eyes were very bloodshot, multiple phlyctens were present around the limbus of both eyes, and the corneal periphery was markedly vascularized. Eczema was observed around the nose and the mouth. The urine contained 250 micrograms of riboflavin per 1,000 cc.

Local treatment was discontinued, and the child received 5 mg. of riboflavin daily. She improved steadily and, after two weeks, the eyes cleared up completely and the facial eczema also improved. The child has remained free from ocular symptoms since that time.

Case 2. A. H., a boy, aged 9 years, had been under treatment at our clinic for eczematous keratitis on four different occasions during the past two years. He was suffering from enlarged adenoids. The ocular condition had always proved very difficult to treat. Superficial and deep vessels appeared in the cornea, and vision was considerably reduced.

When he was first seen this year, both eyes presented the familiar syndrome with blepharospasm, lacrimation, and pain. The bulbar conjunctiva was deeply injected, and the entire corneal circumference was extensively vascularized and showed multiple phlyctens.

The patient received 3 doses of 5 mg. of riboflavin without any local treatment. Within 24 hours both eyes became white and quiescent, and the subjective symptoms entirely disappeared. The patient has not been seen since at our clinic.

Case 3. D. M., a girl, aged 6 years, well developed

* From the Eye Department, Hadassah University Hospital, Jerusalem. Read before the New York Society for Clinical Ophthalmology, May 3, 1948.

Fig. 1 (Stern and Landau). Case 3. Appearance of patient after a severe attack of eczematous keratitis lasting five days.

but somewhat puffed up, had been under our care for several years and suffered from frequent recurrences of eczematous keratitis. She reported to hospital after a very severe attack lasting five days. Very marked blepharospasm, lacrimation, and pain were observed; both eyes were bloodshot, and multiple limbal phlyctens, infiltration of the epithelium of the corneal periphery, and corneal vascularization were noted (fig. 1).

The patient received 5 mg. of riboflavin by mouth twice daily without any local treatment. The following day the condition was unchanged. Treatment with riboflavin, alone, was continued. By the fourth day the right eye had become white, the cornea was clear, and the infiltration around the limbus was entirely gone. The left eye, however, was still injected. By the fifth day both eyes were cured (fig. 2). No pathologic changes were found in the nasopharynx.

Fig. 2 (Stern and Landau). *Case 3.* Appearance of the same patient as in Figure 1 on the fifth day after riboflavin therapy was instituted.

Case 4. R. A., a young woman, aged 23 years, was suffering from intense pain and blepharospasm in the left eye, which showed eczematous keratoconjunctivitis with a large single phlycten at the limbus (fig. 3). The corneal periphery of the left eye was vascularized. The right eye appeared normal. The nose was very narrow, and examination revealed a deviation of the septum toward the left and compression of the left lower turbinate.

The patient had received the usual treatment for the ocular condition elsewhere, without any benefit. Local treatment was discontinued and she received 5 mg. riboflavin by mouth twice daily. After two days the eye was much improved; by the fifth day she was completely cured (fig. 4).

Case 5. A. R., a girl, aged 13 years, showing no scrofulous stigmas, applied to the hospital suffering from acute Koch-Weeks conjunctivitis. She

Fig. 3 (Stern and Landau). *Case 4.* Eczematous keratoconjunctivitis with a large single phlycten at the limbus near the 5-o'clock position.

received 2 gm. of sulfadiazine by mouth during one day. The next day the cornea showed multiple phlyctens and vascularization around the limbus in both eyes. The urine contained 260 micrograms of riboflavin per 1,000 cc. Five mg. of riboflavin by mouth twice daily were added to the sulfadiazine therapy. Two days later the eyes had become white and the intense vascular engorgement had entirely disappeared.

Case 6. T. R., a girl, aged 8 years, well developed but undernourished, sister of the patient in Case 5, suffered from acute Koch-Weeks conjunctivitis. Multiple phlyctens were present in both eyes and the corneal periphery was vascularized (fig. 5). She received 2 gm. of sulfadiazine daily by mouth which cured the acute conjunctivitis entirely within two days, but the eyes remained painful and injected. The picture was now that of a primary eczematous keratoconjunctivitis. The urine contained 255 micrograms of riboflavin per 1,000 cc. The patient received 5 mg. of riboflavin by mouth twice daily and within another 48 hours she was completely cured (fig. 6).

Case 7. A. B., a boy, aged 3½ years, pale and

with enlarged submandibular glands, suffered from pain and lacrimation in both eyes. There was some photophobia. Around the limbus of both eyes 3 or 4 small phlyctens were visible, and the eyes were mildly injected. He received 5 mg. of riboflavin by mouth twice daily. Four days later both eyes were white and clear and the phlyctens had disappeared without a trace.

Case 8. R. M., a girl, aged 13 years, exhibited pellagroid pigmentation of the arms, neck, and ears. She had a deeply furrowed, red tongue. Both eyes were very bloodshot, and the patient suffered from intense blepharospasm and lacrimation. Several phlyctens were seen along the limbus in both eyes and the corneal periphery was vascularized. The patient received 5 mg. of riboflavin by mouth twice daily, and the ocular condition had cleared up without local treatment within four days. Fifty mg. of

Fig. 4 (Stern and Landau). *Case 4.* Appearance of the same eye as in Figure 3 on the fifth day after institution of riboflavin therapy.

nicotinamide was then administered by mouth twice daily, and the dermatitis and glossitis improved steadily. After one week she was cured.

Discussion

The striking effect of riboflavin in a condition known occasionally to be very refractory to the usual local treatment may be explained in either of two ways: (1) The action of riboflavin is a purely pharmacodynamic one, or (2) eczematous keratitis is a manifestation of ariboflavinosis and riboflavin specifically relieves this deficiency.

Bessey and Wolbach[3] were the first authors to describe in detail the occurrence of corneal vascularization with infiltration of the corneal stroma and epithelium in riboflavin-deficient rats. They regarded this condition as a compensating process, whereby blood is brought into closer contact with the deeper

Fig. 5 (Stern and Landau). *Case 6.* Multiple phlyctens were present in both eyes and the corneal periphery was vascularized.

layers of a cornea deprived of riboflavin. Riboflavin constitutes the prosthetic group of the yellow respiratory enzyme on which the corneal cells depend for their respiration. This subtle process can be assumed to be disturbed in any pathologic condition involving the deeper layers of the epithelium and stroma.

Such disturbances may be due to the action of bacterial toxins, of chemical substances released by foreign bodies, and also of noxious metabolic products released in allergic reactions (histamine or histamine-like substances).

It is conceivable that in such conditions the administration of riboflavin relieves the disturbance in the respiration of the corneal cells. It has actually been claimed that riboflavin is very beneficial in a number of corneal diseases such as rosacea keratitis,[4-8] syphilitic parenchymatous keratitis,[1, 9, 10] and trachomatous pannus.[5, 11] Riboflavin has further been shown to have a certain antiallergic action.[12, 13] It is therefore possible that the relief of eczematous keratitis by riboflavin is due either to a nonspecific effect on the respiration of the corneal tissue or to the

Fig. 6 (Stern and Landau). *Case 6.* Appearance of the same eyes as in Figure 5 within 48 hours after riboflavin therapy was begun.

antihistamine action of the vitamin in a disease with undeniably allergic characteristics. However, several points argue against this assumption.

The reports on the beneficial effect of riboflavin in corneal diseases other than eczematous keratitis are open to serious criticism. Its curative effect in rosacea keratitis has been denied by a number of authors.[14, 15, 18] Its effect in syphilitic parenchymatous keratitis seems improbable at first sight, and the correctness of the diagnosis has been challenged in some of the cases published.[5, 7] In trachomatous pannus it has been shown by Landau and Stern[11] that the good results obtained with riboflavin may be explained by the concurrent presence of a true ariboflavinosis.

It is a common experience that eczematous or phlyctenular keratitis occurs almost exclusively in undernourished, scrofulous individuals, or in those on a faulty diet, and it is possible that the administration of riboflavin in these cases relieves a subclinical deficiency. Thus the curative effect would have to be ascribed not to a purely pharmacodynamic action but to a kind of adjuvant treatment. Assuming that this is possible, let us consider more closely the assumption that eczematous keratitis is a manifestation of riboflavin deficiency, particularly in view of the abnormally low riboflavin values in the urine of the three cases in which the urine was examined.

A remarkable clinical similarity exists between eczematous keratitis associated with eczematous pannus and the ocular signs of ariboflavinosis. The corneal vascularization seems to be identical with that in eczematous pannus. The cheilitis and the eczema of the nasolabial fold in ariboflavinosis are strongly reminiscent of the facial lesions in eczematous keratitis, with certain differences probably attributable to differences in age of the respective patients.

Mann[16] and Stern[17] have published descriptions of cases of acute ocular manifestation of ariboflavinosis which are very similar to typical cases of eczematous keratitis. The condition involves acute injection of the bulbar conjunctiva with marked vascularization of the cornea, accompanied by edema of the perilimbal conjunctiva and the peripheral corneal epithelium, which may break down and develop small ulcers. It is very painful and causes intense reflex blepharospasm. It seems to occur mainly in adults but eczematous keratitis may constitute a modified picture of the same disturbance in predisposed children. Our reports on the uniformly satisfactory therapeutic results, together with the subnormal urinary riboflavin values in the cases in which the urine was examined seem to justify the conclusion that these diseases are identical.

In many cases eczematous keratitis seems to be an allergic reaction. The patients frequently are scrofulous individuals with inflamed lymphatic glands, and are almost always hypersensitive to tuberculin. In sensitized humans and laboratory animals the condition may be produced experimentally by instilling a drop of allergen into the conjunctival sac (Calmette's reaction). But it is also known that patients of this type frequently have a craving for carbohydrates which they consume in great quantities, a diet likely to lead to ariboflavinosis.

While we are unable to exclude the possibilty of a pharmacodynamic effect of riboflavin in exzematous keratitis, we are inclined in these cases to ascribe the dominant rôle to ariboflavinosis. Thus it may be assumed that a chronic riboflavin deficiency becomes manifest as an ocular lesion of the above-mentioned type in predisposed individuals, mostly children, but sometimes also in adults.

There seems to be a constitutional element in such a predisposition identical with that defined clinically as the scrofulous habitus. These patients usually show the typical changes in the nasopharynx. It is not quite certain whether these represent concomitant (and coördinated) symptoms, or whether the nasal lesions are prerequisite to the ocular

manifestations. The observations of Feigenbaum[20] in cases of unilateral trachoma (or unilaterally more severe trachoma) suggest that the second possibility is more probable in our cases as well. While lymphatic changes in the nasopharynx were observed in the majority of our child patients, it was noteworthy that our one adult patient had her only ocular lesion on the same side as the nasal lesion.

Phlyctens seem to occur fairly regularly in the course of Koch-Weeks conjunctivitis. In 1921, Feigenbaum[21] found this condition in at least 8 percent of several thousands of patients suffering from this conjunctivitis, and concluded that these complications probably represent the reaction of the scrofulous individual to the toxic irritation by the agent. In a personal communication this author has stated that he repeatedly observed similar phlyctens in scrofulous children during a diplobacillary infection, as well as exactly at the point of contact after irritation of the bulbar conjunctiva by an incorrectly implanted eyelash.

It seems, therefore, that it takes two or more factors to produce the clinical picture of eczematous or phlyctenular keratoconjunctivitis, and that one of these is ariboflavinosis. On the other hand, the fact that many cases of ariboflavinosis never display the acute symptoms of eczematous keratitis seems to suggest that a second factor, in most cases an allergic reaction, is necessary.

In view of the effect of riboflavin in eczematous keratitis, further experimental and clinical investigation will be required to elucidate the question whether this condition is due to a nonspecific pharmacodynamic action of the vitamin, or to the specific relief of a riboflavin deficiency in predisposed individuals. A number of facts seem to point to the second possibility, namely that ariboflavinosis constitutes a decisive etiologic factor.

Summary

1. Riboflavin has a marked therapeutic effect on eczematous keratitis.

2. The question whether this effect is due to a nonspecific pharmacodynamic action of the vitamin or to the specific relief of a deficiency is discussed.

3. It is concluded that a number of factors (nasopharyngeal lesions, infectious agents, or mechanical irritation) in individuals with a constitutional scrofulous disposition may release the pathogenic mechanism producing eczematous keratitis, but that ariboflavinosis is the essential basic condition.

NOTES, CASES, INSTRUMENTS

SIMPLIFIED EXTERNAL EYE PHOTOGRAPHY*

PHILIP H. LANDERS, M.D.†
Baltimore, Maryland

Photography of the external eye is practical with minor modifications of an Argus model C-3. This is a medium-grade, 35-mm. camera with synchronized flash-bulb attachment. On reviewing the description of the mechanisms devised by Bedell,[1] Bogart,[2] Irvine and Stimson,[3] Katzin,[4] and Knighton,[5] it is evident that the stress has been on securing perfect focus and on being able to maintain that focus during the time necessary to manipulate the camera and lighting equipment.

In this camera, the emphasis is on creating a system having greater depth of focus, accuracy of aim, and speed of operation. Minor movements of the patient are not important. It is therefore possible to discard the table, head-holding frame, camera stand, complicated electrical circuits, and interchangeable mounts for the focusing ground glass and camera. The elimination of this complex, costly, and cumbersome equipment frees the camera for use in the clinic, on the wards, and in the operating room. These improvements are obtained by a combined fixed aiming and focusing device and a light of sufficient intensity to reduce the lens aperture to a minimum, thereby increasing the depth of focus.

In the construction of the optical system, parts made by the original manufacturer were preferred. This system consists of the original camera, which is set at 5-foot focus, and a combination of portrait lens chamber and sunshade, which screw to the lens mount. The portrait lens chamber contains a plus-3 lens and a disk of Wratten No.-2 gelatin filter. A plus-16 lens ground from a cataract lens blank, is mounted inside the front of the sunshade. This combination of camera and lenses has a focus of 48 mm., which was determied by the ground-glass method. Chromatic aberrations need not be considered. Spherical aberration is minimized by using a large diameter lens for the plus 16, so that only the central portion is used. The residual aberration is negligible.

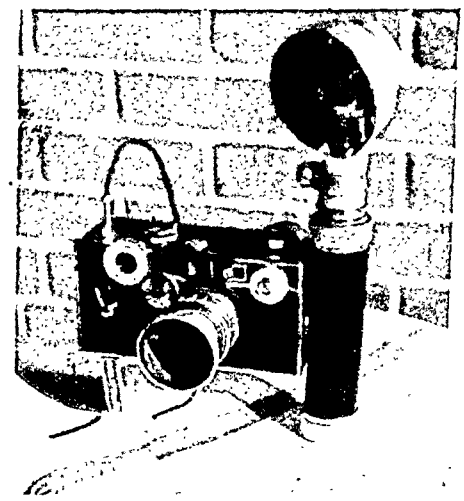

Fig. 1 (Landers). Argus C-3 camera with modifications.

A curved metal rod is bolted to the sunshade in such a manner that the tip of the rod is exactly 12 mm. below the center of the photographic field, and is exactly at the 48-mm. distance from the front lens. The size of the object and of the picture is identical. The tip of the rod is at the margin of the field but does not show in the picture.

The light source is a No.-5 press flash bulb, and the film is indoor Kodachrome (type A). The light temperature of the press flash bulb No. 5 is not perfectly adjusted to type-A Kodachrome, but this is corrected by the filter mentioned above.

* Published with permission of the chief medical director, Department of Medicine and Surgery, Veterans Administration, who assumes no responsibility for the opinions expressed or conclusions drawn by the author.

† Resident in ophthalmology, Veterans Administration, Fort Howard, Maryland.

The standard reflector for the camera cannot be used because of the size of its reflection on the cornea. A small metal shield is therefore substituted. This shield is painted black on the inside except for the area immediately behind the bulb. This is to minimize further the size of the corneal reflection. The front of the reflector has a transparent plastic cover to prevent possible injury to the patient from an exploding bulb.

With the press No. 5 bulb only 19 cm. from the eye, the light intensity permits the lens aperture to be decreased to f-16 or smaller. This factor is important because the depth of focus of the system is over 6 mm. at f-18, and only 1 mm. at f-3.5.

The speed of the shutter is not effective until it is faster than 1/100 second because of the few thousandths of a second during which the flash lasts. If it is desirable to

Fig. 2 (Landers). Demonstration of operation of camera.

reduce the light more than is accomplished by an f-18 opening, the shutter speed can be set faster.

In actual practice, this camera can be used without loss of more than a few moments, or can be operated by a nurse or secretary. The mode of operation is most un-

Fig. 3 (Landers). Illustration of a normal eye showing size of field and depth of focus.

complicated. The camera is kept loaded and with the proper adjustment set, with the exception of the aperture which is adjusted to the complexion color. The patient is warned not to be frightened at the flash, and the camera is held before his face in such a manner that the tip of the focusing rod is 12 mm. below the center of the desired field and in the proper plane. The picture is then taken instantly, and a notation made.

The same camera as described, with an additional portrait chamber attachment using a plus-3 lens, is excellent for photographing both eyes in cases of squint, or anything requiring a full face. This is accomplished by using 23- or 32-cm. distances with approximately the same settings as to shutter speed and aperture.

In conclusion, it would seem to be of more than casual importance that, with the present trend toward more and more complex, elaborate, and expensive mechanisms, a simple, effective, and inexpensive device can be constructed for making permanent color records of external and anterior eye conditions.

OCULAR MANIFESTATIONS IN COCCIDIOIDOMYCOSIS

JESSE M. LEVITT, M.D.
Brooklyn, New York

Coccidioidomycosis[3] is a disease caused by a fungus, Coccidioides immitis. It is considered to be primarily a disease of rodents, transmitted to man when dusts that contain spores are inhaled. It is endemic in the San Joaquin Valley in California and in other southwestern states, and has been seen in other parts of the United States. During the war the condition became important because several thousand soldiers, who were stationed in Army camps in the Southwest, probably became infected. Some of these men will undoubtedly develop active pulmonary lesions within the next 10 years.

The lungs are usually first infected through the inhalation of the spores and the infection is spread to various parts of the body by continuity and through lymphatic and vascular channels. Up to the time of World War II, only a severe general form of the disease, resembling tuberculosis, had been recognized. It is now known that in most instances the infection is benign, simulating influenza or virus pneumonia, and lasts usually 3 to 6 weeks. X-ray studies of the lungs in the mild form resemble those shown in virus pneumonia, while in the chronic form they resemble those in tuberculosis, with cavitation a prominent feature.

The causative organism may be recovered from the sputum and other infected body fluids and tissues. Skin tests with Coccidioides-immitis antigen may be helpful in diagnosis. A positive skin test does not necessarily indicate active coccidioidal infection. A negative test is believed to exclude the infection, except where the infecton is too early for sensitivity to have developed. The pathologic condition is essentially a granuloma greatly resembling the lesions of tuberculosis.

The observation of changes in the ocular fundi in a case of coccidioidomycosis is worthy of record. To my knowledge, no previous report has appeared in the literature. Because of the protean nature of the disease and its great similarity to tuberculosis and the other granulomatous diseases, one would expect some cases to have an involvement of the uveal tract and retina.

Charles E. Smith[1] stated that the patient with coccidioidomycosis may exhibit typical phlyctenular conjunctivitis. Willett and Weiss[2] reported the occurrence of conjunctivitis in 4 of 100 cases. With the exception of conjunctivitis, ocular involvement in the course of the disease has not been mentioned in the literature.

REPORT OF A CASE

Following is the report of the eye findings in a case of coccidioidomycosis of the primary pulmonary type. The diagnosis was established by the isolation of the causative agent, Coccidioides immitis, in the sputum. Striking changes were observed in the vitreous chambers and fundi.

History. Sergeant D. T. L., white, aged 20 years, a patient in the medical department of Fletcher General Hospital, Cambridge, Ohio, was referred to me by Dr. Frank J. Mellencamp on August 14, 1943, because of visual disturbances of both eyes.

While overseas he became ill with what was initially diagnosed as lymphocytic choriomeningitis. He was hospitalized in the

British 40th General Hospital in British West Africa and was subsequently evacuated to the United States.

The only complaint on admission to Fletcher General Hospital was pain in the back and legs. Physical examination, including the chest, was negative. X-ray studies of the chest revealed an infiltrate in the right middle lobe which had the appearance of a tubercular lesion. A fungus, presenting typical structure and cultural characteristics of Coccidioides immitis, was recovered from the sputum.

The patient complained that vision of the left eye first became blurred for intervals of ½ to 1 hour and that later similar episodes were experienced in the right eye. For two weeks prior to my examination he had noticed "shimmering spots" first in the right eye and then in the left eye.

Eye examination revealed vision to be: O.D., 20/30, J1; O.S., 20/20, J1; correctable to 20/15, O.U., with a compound hyperopic astigmatic lens of moderate degree; no significant muscle imbalance; small discrete follicles in the palpebral conjunctivas of both lower lids; white globes; small corneas; pupils that reacted actively to light and accommodation.

The pupils were widely dilated with 4-percent solution of homatropine hydrobromide. The anterior segments of the globes were entirely normal on slitlamp study. Both vitreous chambers were clouded by whitish-appearing, globular opacities which, while movable, maintained a relatively fixed position, indicating a basically normal vitreous structure. The optic nerveheads were of good color with slightly indistinct margins due to the astigmatic refractive errors. The nerveheads were not elevated.

In the right fundus there were several small oval-shaped masses of what appeared to be whitish connective tissue, attached to the retina and moving up and down in the vitreous The bases of these masses at the level of the retina were hemorrhagic. These were mostly evident in the nasal and lower fundus about 1½ disc diameters from the margin of the optic disc. Just below the optic disc, there was a denser strand of similar tissue projecting into the vitreous. A like picture was observed in the left eye with a lesion also present below the left disc. There was no abnormality of the retinal blood vessels. The macular zones were free of pathologic manifestation.

The diagnoses were: (1) follicular conjunctivitis, benign; (2) vitreous opacities and retinitis of proliferative type, considered evidence of probable localization of the causative agent in the eyes; (3) compound hyperopic astigmatism, bilateral.

On the day following my examination the patient left the hospital on a 30-day sick furlough. On his return on September 16, 1943, I reëxamined his eyes and found the vitreous chambers entirely clear and the fundi perfectly normal. There was no trace of the previous pathologic findings.

The lesions noted in the retinas in this case, and their rapid disappearance, offer a striking parallel to the type of granulomatous lesions noted in other parts of the body, and the frequent rapid clearing of the physical signs and pulmonary changes visible to X ray.

Summary

The main features of coccidioidomycosis are presented.

Changes in the vitreous chambers and ocular fundi in a case of coccidioidomycosis are described.

Because of the protean nature of the disease and its great similarity to tuberculosis, one would expect some cases to have intraocular involvement. It is suggested that the ocular fundi should be watched during the course of the disease.

It would not be amiss to include a coccidioidin antigen skin test in the etiologic survey of cases of endogenous ocular infection, particularly in veterans of World War II.

PERIPHERAL IRIDECTOMY IN CATARACT SURGERY

A. C. HILDING, M.D.
Duluth, Minnesota

In cataract extraction, I have observed a practice in the use of peripheral iridectomy which does not seem to be quite rational. A peripheral iridectomy is made in the 12-o'clock meridian when there is also a single corneoscleral suture in the same meridian. The reason given for making the iridectomy is to furnish a communication between the posterior and anterior chambers. This is necessary, it is explained, because it is the aqueous in the posterior chamber which causes iris prolapse, not that in the anterior chamber.

This fact has been established for a long time. However, there is another fact which seems to have escaped notice very largely; namely, that, at the time of iris prolapse, there is no anterior chamber. If there were then the pupil could serve better as a communication between the anterior and posterior chamber than a small peripheral hole. The communication must be between the posterior chamber and the out-of-doors. With the escape of its aqueous the anterior chamber has become merely a potential space, and the iris lies in such close contact with the cornea as to form virtually a water-tight seal. It is under these conditions that that portion of the iris which overlies the breach in the incision begins to herniate as the aqueous in the posterior chamber makes pressure. Only one of two things will stop it: either cessation of pressure or escape of aqueous through a hole in the iris which coincides with the breach in the incision. If the iridectomy does not coincide with the breach in the incision, the aqueous will not escape, and prolapse takes place. Therefore, iridectomies at other points, even though fairly close, will not prevent the prolapse.

The incision, when it gives way, usually does so in the middle of the longest unsupported arc. It would not give way at the site of a single corneoscleral suture in the 12-o'clock meridian. Therefore, a peripheral iridectomy in this meridian would seem to be useless. If the incision gives way, it would do so somewhere between this central suture and one or the other of the angles of the wound. If peripheral iridectomies are to be used with a single suture in the 12-o'clock position, there should be two of them, and they should be placed respectively at about the 10:30- and 1:30-o'clock positions. If a single peripheral iridectomy is made at the 12-o'clock position, then there should be at least one suture on each side midway between the iridectomy and the extremities of the incision.

Either of these procedures would give at least three points of protection along the arc of the incision. according to some previous studies,* 4 or 5 points of protection are much better than 3. They may be furnished by 2, 3, or 4 corneoscleral sutures, combined respectively with 3, 2, or 1 peripheral iridectomies. Any one of these combinations gives reasonable protection against prolapse, but the iridectomies should be

*Hilding, A. C.: Experimental and clinical studies on certain safety factors in closure of cataract incisions. Am. J. Ophth., 28:871-885 (Aug.) 1945.

placed between the sutures and not under them. The sutures can all be placed before the anterior chamber is opened.

626 Medical Arts Building.

STREPTOMYCIN IN OPHTHALMOMILIARY TUBERCULOSIS*

PETER SYKOWSKI, M.D., AND WALTER LAWRENCE, M.D.†
Schenectady, New York

Recently McDermott and others‡ reported their results in the employment of streptomycin in the treatment of tuberculosis in human beings. We wish to present a case of ophthalmomiliary tuberculosis treated with streptomycin.

REPORT OF CASE

History. R. Q., a 28-year-old white woman, married, was well until May, 1947, when pharyngolaryngeal symptoms became apparent. These were characterized by dsyphagia, hoarseness, and pharyngodynia. For several months prior to this, increasing fatigability was observed. Until July, 1947, her laryngopharyngeal symptoms persisted. Then, an otolaryngologist was consulted and a diagnosis of laryngophthisis was made. Pulmonary X-ray studies revealed an acute miliary tuberculosis. She was admitted as a patient to the Glenridge Sanatorium on August 9, 1947.

Physical Examination. The patient was poorly developed, poorly nourished, and thin, appearing acutely and chronically ill. There was a moderate amount of pallor of the mucous membranes. Only the arytenoid area of the larynx was visible. It was the site of marked edema and of severe injection; on its anterior surface a thin, grayish, diffuse exudation was present. There were no abnormal signs in the lungs.

Laboratory Data. Pulmonary skiagrams showed a fine, disseminated miliary type of infiltration scattered evenly throughout both lungs.

Ophthalmic Examination. Biomicroscopy and ophthalmoscopy revealed negative findings in the cornea, aqueous, iris, lens, and vitreous. The fundus of the right eye showed 5 small, pinpoint-sized, gray-white nodules. Three of these nodules were 2½ disc diameters from the papilla at the 1-o'clock meridian; 2 were at the 6-o'clock meridian. There were no pigmentary changes in the areas adjacent to the nodules.

Treatment and Course. Two days following admission, streptomycin therapy was instituted, 1½ gm. daily in 6 divided doses. The laryngeal symptoms showed an almost immediate response, and the general response was unusually satisfactory. Comparative pulmonary X-ray studies, one month after admission, showed less density, giving the impression of beginning resolution. During the second month after admission, no definite change occurred. By the third month, however, there was definite resolution, with marked clearing of the infiltration throughout both pulmonary fields—the most striking change in the entire serial studies.

At this time, an ophthalmoscopic examination showed that the choroidal tubercles situated at the 1-o'clock meridian had completely disappeared and those at the 6-o'clock meridian previously easily detectable were scarcely perceptible.

SUMMARY

This report of a case of ophthalmomiliary tuberculosis, treated with streptomycin, shows that the use of streptomycin definitely altered the course of the miliary choroidal tubercles and sponsors the conclusion that streptomycin therapy is of value in arresting miliary choroidal tuberculosis.

1330 Union Street.

DR. PERCE DELONG, *chairman*

OPHTHALMOSCOPY AND OPERATIONS FOR HIGH BLOOD PRESSURE

DR. ARTHUR J. BEDELL (guest speaker) of Albany, New York, said that the majority of hypertensive patients are free from symptoms, and the high pressure is discovered on routine physical examination.

The ophthalmologist often makes the original diagnosis of hypertension and inaugurates the investigations which may lead to an operation. The prime symptoms for which he is consulted are intense, persistent, treatment-resisting, generalized headache, or nuchal, occipital, or frontal distress, frequently most intense in the early morning hours.

Because of visual defects a patient may visit the ophthalmologist who recognizes the causative significance of the vessel changes, the congestion of the fundus, the lack of retinal definition, the retinal hemorrhages, the retinopathy or the papilledema.

Ophthalmologists should be able to state with reasonable certainty that a given fundus pattern indicates a favorable postoperative outcome, one of doubtful value, or a disappointment. They must know the life history of the retinal variations, and estimate the life expectancy of the individual patient. They should render a concise but genuinely explanatory report, including an opinion based on a knowledge of the favorable and unfavorable results following operation, and upon an understanding of the fundus signs.

If this is done, more cases with a good prognosis will be operated upon, and fewer of the hopeless subjected to the trying ordeals from which little or no benefit can be expected. The prognosis is based on the state of the retinal vessels.

The ophthalmoscopic signs which determine the feasibility of operation are correlated. Many exceptions may be made to them and occasionally what seems to be a hopeless case may, by operation, be given a few more years of life.

It must be remembered that hypertension is a complex manifestation of many factors all of which must be evaluated before an accurate prognosis can be given. All advice is predicated on the integrity of the kidneys, heart, and cerebral vessels.

From the ophthalmoscopic standpoint, there are two types of hypertension: one in which there are very slight vessel changes even after many years of high pressure. Eventually, the majority of such patients die from a cerebral or cardiac accident without ever having a retinopathy.

The other, labelled malignant, should be called fulminating because of the rapidly progressing retinopathy. Frequently at the time of the initial examination there are extensive exudates and hemorrhages with or without retinal edema and an irregular outline of the blood column, a spasm, or white-walled sclerotic vessels.

The fulminating type is comparatively seldom engrafted upon the simple form of essential hypertension. There is, however, no definite duration of the benign stage and no reliable guide by which we can prognosticate the imminence of the signs which almost invariably foretell an early death. It is to these potentially fulminating cases that the surgeon's attention is often directed, for without help, such patients are doomed. As a last resort, an operation may be tried; for medical treatment is ineffective.

The severe cases of retinopathy are usu-

ally associated with signs of marked kidney dysfunction, so that they rarely reach the standard of kidney efficiency demanded by the most careful surgeons.

Patients with papilledema and extensive neuropapillary edema should not be subjected to operation.

Discussion. DR. W. EMORY BURNETT: It has been a great pleasure to hear Dr. Bedell, and to consider certain additional helps in choosing patents for sympathectomy for hypertension. As a surgeon, I am a little out of my depth tonight, but can discuss some of the other considerations besides the eyegrounds at least in our selection of these patients.

I think the only thing we have to contribute tonight is the consideration of the patient as a whole, not depending entirely on eyegrounds, as much as we would like to, but feeling that there are multiple other considerations which have to be taken into our estimate. We have been watching very carefully the results of the operations, and comparing them with the forecasts. We have approximately 60 cases now on which we have operated. Some of them are too recent to evaluate properly, and, therefore, it is hard to say what is of great value and what is not.

We started out using the criteria which had been set up for us by the then known authorities in this work, particularly Peet and Smithwick, but none of the items have been too reliable or accurate, and often there is great difficulty even using all of them. Actually the tests on which we have depended most in the past two years have been the production of sympathectomy of a temporary nature, such as tetra-ethyl-ammonium bromide, or chloride, and ascending spinal or ascending caudal anesthesia, which imitate the operation for a few minutes, the latter more accurately than the former, because the tetra-ethyl-ammonium bromide is a total sympathectomy for a few minutes and the spinal is a selective or partial one. So far these have been the best forecasts that we have found. Although eyegrounds have helped tremendously, we have to realize that what is seen is the effect in a local situation, and this does not necessarily mean the entire body is similarly affected.

Another thing that may contribute to the inaccuracy of our correlation between results and forecasts is the fact that, until recently, certain sympathectomies have been rather limited, and limited sympathectomy may not be sufficient to produce the desired effect; thus, the accuracy of forecast is not actually disproved. The eyegrounds and other studies may indicate that a patient is a good prospect, that he is very likely to obtain benefit from sympathectomy. If the operation is too limited to interrupt all nerve connection with the splanchnic plexus that does not actually prove or disprove the point.

Because of this, we began not quite two years ago to do a rather extensive sympathectomy more in the nature of Grimson's type, although he was doing complete lumbar removal as well. We have not done that, but have utilized a transpleural approach so as to get to the entire thoracic chain and easily approach the upper portion of the lumbar chain, and have almost routinely, not quite universally, removed ganglia from thoracic 2 to lumbar 2, inclusive, thus leaving very little of the sympathetic chain still functioning.

The results of this more extensive operation are definitely better immediately and, probably when we have followed these patients long enough to evaluate the late results, we may be able to say that the eyegrounds furnish much more accurate forecasts than we are now prone to believe, probably on the basis that we have not given them a chance to be accurate by doing adequately the job which they indicated we should do.

Results of this more extensive sympathectomy have been much better not only in the percentage of patients who have improved, but in the degree of improvement so that we no longer have to hunt around for 10 mm. of diastolic drop. We are rather disappointed if they do not get 30 mm. or better. There have been some failures in our group. There have been failures despite the in-

clusion of spinal anesthesia and tetra-ethyl-ammonium bromide administration, but they have not been nearly so numerous as previously.

Dr. Frederick Bothe: We surgeons have a long way to go to appreciate the finer points of the eyeground study with which you gentlemen are so familiar. However, there are a few things that I wish to discuss from that angle.

You are all familar with the excellent results that Peet has obtained in cases of malignant hypertension. In the early cases I was reluctant to do a sympathectomy once the case was diagnosed as one of malignant hypertension. I did two cases at the request of the patients after I had told them I did not feel sympathectomy would help them. The symptoms, particularly headache, were relieved in both instances, but otherwise they were not benefited. Others have experienced results comparable to mine in malignant cases.

This variation in results could be explained on the grounds that the criteria of eyeground changes denoting the beginning of malignant hypertension are variable in the minds of ophthalmologists.

Sympathectomy was performed in cases of essential hypertension to reduce the vasoconstriction. This constriction is either neurogenic or humoral in origin. In the early sympathectomies only the splanchnic nerves were removed. As the results were studied, some surgeons felt that an improvement could be obtained if a more extensive sympathectomy was performed. Today there are various procedures employed.

Griscom has performed a very radical procedure. He has removed all the thoracic and lumbar ganglia in addition to the splanchnic nerves and the celiac ganglion. Others are not so radical. The procedure Dr. Burnett just described is more radical than that which I use.

At present my routine is composed of excision of the sympathetic cord from thoracic −10 to lumbar −2 ganglion, inclusive, with removal of the splanchic nerves and a piece of the celiac ganglion. We hope that future analyses of the results will decide for us whether the conservative or more radical procedures give the best remote results. The improvement in the eyegrounds seems to be about the same with the various procedures.

In the past few years we have increased the scope of the use of sympathectomy. In the early work it was felt a sympathectomy was not indicated if a patient gave a history of a serious cardiovascular catastrophe. In the light of the excellent results that Peet reported in this type of case, I have tried a few in the past several years. My patients had a history of either a hemiplegia or coronary occlusion. These cases have been followed 2½ to 3 years, and their improvement has justified the procedure in carefully selected cases.

One word as to the return of the hypertension. Let us not forget we are not in any way attempting to cure the hypertension. All we hope to do is to produce a safety valve for these patients in an effort to prevent or postpone the cardiovascular catastrophies characteristic of this disease. Sympathectomy increases capacity of the closed system through which the blood circulates. When the spasm again reduces it to the preoperative capacity the pressure returns, but it is hoped the safety valve persists. Results universally show that many patients have symptomatic relief even though the blood pressure returns to the preoperative level within 3 to 6 months postoperatively.

Dr. Glenn G. Gibson: Dr. Bedell is better equipped than any man in the world to bring this message to us, because of his extensive studies on over 2,000 cases of hypertension, which he has recently reported, and also because of his unexcelled fundus photographic material.

The surgery of hypertension has placed an additional burden on ophthalmologists in their diagnosis and classification of these vascular disturbances. When an ophthalmologist is called in consultation on a patient with hypertension, he is asked to make a prognosis. That prognosis is composed of

two parts. The first part is how much damage has been done to the patient's vascular tree. The criterion for that is how much sclerosis is present.

Dr. Bedell has mentioned that the classification of sclerosis into four main types, as advocated by Wagner, is very difficult to do correctly, and he objects to it on that basis. I agree with his objection that it is difficult to learn. In teaching residents, it is one of the most difficult tasks that we have in the whole field of teaching of ophthalmology. However, once students of ophthalmology do learn this classification, they have a tool which is very useful. At least that has been my experience in the past 15 years.

The thing I was taught that stood up best under clinical trial is the classification of hypertension into four grades of sclerosis as taught to me by Dr. Henry Wagner, who devotes most of his time to the classification of these vascular diseases. He believes thoroughly in this grading of sclerosis of the arterioles, and we have found it to be a very useful thing in the study of these cases.

The second part of the prognosis is what is the future course of this case most likely to be. We feel we can estimate this to a certain extent by dividing hypertensive cases into two main groups. The first of these is a chronic hypertension which takes a very chronic course, and the second is what we refer to as a more active type of hypertension which runs a more fulminating course.

What are the eye findings which differentiate these two different clinical courses? In a case of chronic hypertension, the most important one is arteriovenous compression. We attach more significance to arteriovenous compressions than Dr. Bedell seemed to employ in his cases. We feel that arteriovenous compression is the most reliable sign of chronic sclerosis. The other sign which is most important in the chronic group is the color of the vessel. In early chronic hypertension there is a mild accentuation of the reflex stripe and, as this condition becomes more marked, the change is that of the so-called copper-wire artery. The silver-wire changes represent the more marked degrees of chronic sclerosis.

Turning to the other extreme, what are the changes associated with active hypertensive disease? They are: (1) Marked attenuation; (2) presence of angiospasm and intermittent caliber constrictions; (3) presence of edema localized in the retina to an arterial distribution; and (4) presence of the various types of retinopathy, particularly edema of the discs. These signs are the signs of activity of the more rapid fulminating types of hypertension.

Dr. Bedell has made some very dogmatic statements, and has some pretty set ideas on which cases are suitable for surgery and which are not. We feel that our data are much too incomplete, both as to number and as to duration, to assume any dogmatic point of view about which cases should be surgical and which should not. Therefore, what we have to say in this regard is to be taken as conjectural and not as definite established fact.

Analysis of our data suggests that the prognosis is best in those cases where there is grade-one sclerosis. I am not sure that is a very significant statement, because the prognosis in grade-one sclerosis is better than in the more severe grades of sclerosis. The next trend that we find in our data is that those cases which show signs of activity, mainly the vasospastic group, are the ones which show the most convincing evidence of improvement following surgery. Conversely, the more chronic cases show less encouraging results. It is only fair, however, to point out that these are only trends, because there are examples of successful results in both groups, but by and large the more active group shows the better response.

One of the main difficulties in this problem is to differentiate between the retinopathy of acute vasospastic hypertension and retinopathy of malignant hypertension. Let us be fair about this and admit that the classification of the serious forms of this disease is unsatisfactory.

Dr. Bedell implies he does not like the term malignant hypertension. I am only too willing to agree with him that the classification is unsatisfactory as it stands. I think that one of the important contributions of surgery in this field may be that classification and understanding of hypertension will be on a higher plane than it was in the pre-surgical days.

Early in the history of this condition, we felt that the main benefit from surgery was relief of symptoms, and that, even though the blood pressure dropped temporarily, there was not much in the way of permanent value to be had from this operation. We particularly felt that malignant hypertension was much too serious a disease for surgical approach.

Dr. Burnett has operated on a number of cases of malignant hypertension and, from a review of the records, they seem to show the best results. Dr. Bedell states that these cases should not be operated and, on a logical basis, I would be inclined to agree with him, but some of the cases that have had malignant hypertension have shown a number of different signs and symptoms of improvement. They have received benefits which could not be expected by the ordinary remissions that occur in these cases. The results of Dr. Burnett's surgery have changed my opinion of this problem from one of complete disbelief in the value of the procedure to one of cautious enthusiasm. The postoperative fundus findings are unpredictable, but are dramatic in some cases.

Dr. Arthur J. Bedell (closing): Dr. Burnett, I am deeply grateful to you. You have given us the benefits of your mature deliberations. I was told before I came to Philadelphia that the address of a guest was not discussed, and I asked that the habit be broken. How fortunate that the rule was laid aside. You were gracious to come and tell us about your long experience in the surgical treatment of hypertension.

You, Dr. Burnett, have added much to our knowledge. I have, of course, read the literature, and as a result have been left in a state of confusion. The reports from the various clinics have shown that some surgeons go high in the thoracic region and some low in the lumbar, and all have claimed good results; so I have felt that perhaps it was the skill of the operator rather than the extent of the operation that led to the favorable outcome.

I did not tell ophthalmologists the details of operations for I felt that, if they were sufficiently interested, they would read about them. You, however, have saved them the effort, and I am sure they are grateful to you for the clear exposition of the nature of the present operation.

Dr. Bothe, you have added much to the value of the exposition. You have helped us understand some of the problems you encounter and overcome. You have referred to the Peet summaries. In going over his last report, I believe it is the latest one, he reported 1,500 operations. From an ophthalmic standpoint, and, of course, that is all I am discussing, his citations are rather incomplete. He had done things that I would not wish to have done to me. He has reported some conclusions at variance with other surgeons.

Your statement regarding hemiplegia has been of great interest for your good results are surprising. They cause us to pause, and to be more cautious in excluding this type of case from possible benefits of operation.

Dr. Gibson you have added much to the value of the paper, because you have amplified and clarified many of the points which I have touched upon, and brought into relief some questions in which there is a difference of opinion. Your stand has been made so clear that we all recognize your extensive experience and the value of your deductions.

M. Luther Kauffman,
Clerk.

MEMPHIS SOCIETY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

March 9, 1948

Hysterical amblyopia

Dr. James E. Wilson reported that J. F. W., a 36-year-old white man, complained of sudden loss of vision. His wife gave a history that he had always been quite a nervous person. He said that his father at the age of 33 years had suddenly lost his vision while walking down the street. His father's vision never returned. Report on the father from a soldier's home reported optic atrophy, cause undetermined.

For a few days before coming to my office he had said that he had felt a roughness and saw specks before his eyes. On January 6, 1948, his vision was good when he went to bed but when he awoke on January 7, 1948, he could not see.

At interview on this date he denied seeing light but at examination admitted seeing 20/200. The pupils reacted normally. The fundi were normal except for a slight temporal pallor of the papilla and a temporal choroidal crescent. Extraocular movements were normal, as were his eyes in every other respect. A blind person will face the examiner to converse but Mr. W. sat semirigid not turning his head or eyes. Spinal puncture and encephalogram were normal. Field examination could not be done.

His wife was told that he had hysterical amblyopia and that his vision would return as suddenly as it had left him. In spite of warning she told this to the patient so that the planned treatment could not be effectively used.

He was hypnotized and given sodium pentothal anesthesia without establishing his ability to see. Reëxamination on January 30, 1948, showed his eyes and condition to be unchanged. On February 20, 1948, at a special church prayer service Mr. W.'s eyes were anointed with olive oil and his vision suddenly returned. Now he is planning to enter the ministry.

Welfare agencies seemed determined to help this "blind man" but were advised that any help would prolong his disability.

Removal of orbital tumor

Dr. J. Wesley McKinney reported the case of J. S., a girl, aged 11 years, who was first seen in the Pediatrics Department of John Gaston Hospital on April 24, 1945. At that time she had a marked swelling of her right eye. This swelling had increased in the past five days, but the right eye had always been larger than the left. A rash was present over the entire body, there was a marked photophobia, and the patient was having frequent headaches.

Temperature on admittance was 103°F. Physical examination revealed a marked swelling of both upper and lower lids of the right eye. The cornea was not ulcerated and the fundus looked normal. There was a marked swelling of the nasal mucous membranes which were red and congested. A vesicular eruption covered the entire body.

Diagnosis on admittance was (1) chicken pox and (2) orbital abscess or cellulitis possibly from rupture of ethmoid or antrum sinuses.

The patient received penicillin, sulfadiazine, cold compresses to the eye, and supportive treatment. Two days after entrance, an external ethmofrontal drainage and a simple antrotomy were performed. No pus was found in the ethmoids or frontal sinuses and only a small amount of pus was encountered when antrotomy was done and the conjunctiva incised and probed. She improved under treatment and was discharged on the 15th hospital day, reporting to the Ophthalmology Clinic one week later.

At this time the examining doctor stated that the right eye showed marked exophthalmos with a dilated pupil which was fixed to light. The right fundus revealed a small red area in the macula, a bit larger than the

size of a pinhead. Vision was: O.S., 20/20; O.D., gross perception of light only. The exophthalmos, as noted, was extreme. No measurements were made since no exophthalmometer was available in the clinic. A tumor mass could be palpated deep in the orbit.

She was sent back to the hospital for removal of the orbital tumor. Repeated X-ray studies were entirely negative. However, on June 22, 1945, the orbit was entered by the Krönlein method. A wedge-shaped sector of the lateral wall of the orbit was resected and left attached to the periosteum. By finger dissection in the depths of the orbit, a well-encapsulated tumor was separated from the optic nerve. It was found to be attached by a broad lease to the greater wing of the sphenoid. There was rather profuse bleeding on reaching the base of the tumor. A tonsil snare was looped over the tumor to the base which was cut by this instrument. Fortunately, there was no further bleeding. The tumor was apparently a larger hemangioma. The child made an uneventful recovery. Vision is now light perception; ocular movements are normal.

Pencil penetrates orbit

Dr. William F. Klotz presented G.E., aged seven years. The child was seen about one hour after having fallen on her way to school, sticking a pencil into her face. She had a gruesome appearance with one inch of the eraser end of the pencil protruding from the face about the level of the lower orbital margin. X-ray films showed the pencil extending back through the orbit and the point sticking into the body of the sphenoid. It appeared to stop within about 2 mm. of the sella turcica. The child was anesthetized with pentothal and the pencil, stuck tightly, was removed with a rotary motion, leaving no portion in the wound. The wound healed within 2 or 3 days without infection, leaving a very small linear scar. She now has vision of 20/20, normal visual field, and no disturbance of any of the extraocular muscles. The mark on the pencil shows the depth, measuring 6 cm., that the pencil had penetrated. The X-ray films show the pencil in position and the postoperative X-ray picture shows no indication of a foreign body.

Ammonia burn of corneas

Dr. M. B. Seligstein presented a case of ammonia burn of both corneas. While the patient was tearing down a 3-inch ammonia pipe on December 29, 1946, some of the liquid squirted through a leak in the gasket in the values, and hit his face, catching the mouth, eyes, and lids. He was sent to St. Joseph's Hospital by the company physician.

Examination the next day showed that both lids and eyes were inflamed, as was the conjunctiva. The cornea of the right eye showed a large stain involving three fourths of its area. A streak about 1½-mm. wide spread from the center of the left cornea toward the 3-o'clock position. Holocaine and metaphen ointment were applied, together with cold boric compresses and atropine. Daily treatment at the hospital brought marked improvement and the patient was allowed to come to the office for treatment.

On January 4, 1947, the left cornea was clear and showed no staining. The right cornea still stained below the center. Gradual improvement of the right eye was noted until January 15th, when the patient complained of severe pain in the right eye. Tension was 28 mm. Hg(Schiøtz) and there was again well-developed staining of the cornea. He was put on eserine ointment for 24 hours but severe pain continued.

On January 16th, there was a small amount of pus in the anterior chamber of the right eye. Precipitates on Descemet's membrane, tension of 32 mm. Hg, and posterior synechias were present. Instillation of 10-percent neosynephrin was started at once, and in addition atropine ointment (1 percent) was used.

By January 20th, the hypopyon had disappeared, the pupil was semidilated, tension

was 26 mm. Hg, and 10 cc. of sterile milk were injected. The next day, tension was 26 mm. Hg, and the patient was still being treated with neosynephrin, atropine, and dionin. Iritis was still present and the cornea stained below. During the day, the patient was fairly comfortable but had pain at night.

On January 24th, tension returned to normal and he was comfortable, with no pain. Since that date, tension has remained normal. Synechias were present but the pupil was kept partially dilated. There was still cloudiness of the cornea in the area below the deepest burn but it did not stain.

The patient again had severe pain and watering of right eye on March 4th. Examination showed a well-developed staining of the cornea, but tension was normal. Atropine and dionin were used in addition to 10-per-cent neosynephrin. There is still some staining present below; some corneal opacity is present; the pupil is semidilated; tension is normal; vision is 20/200.

LATE FISTULOUS WOUND WITH EPITHELIAL INGROWTH FOLLOWING CATARACT EXTRACTION

DR. PHILIP MERIWETHER LEWIS presented O. G. H., a white man, aged 57 years, with an unusual series of complications coming on late after an apparently successful cataract operation.

The patient had noticed his vision failing for about one year. He had been under the care of Dr. J. B. Blue who diagnosed a posterior cortical cataract of both eyes and referred him for operation. Corrected vision was 20/100, J14 in each eye.

On January 30, 1947, a combined intracapsular extraction was performed on the left eye and four days later the same procedure was done on the right eye. No difficulty was encountered and no vitreous was lost. Stallard sutures were used on both eyes. The anterior chamber was slow to become restored in each eye, the left requiring 4 days, and the right, 6 days. Convalescence was otherwise uneventful. On April 1st, he obtained on refraction a vision of 20/20 plus in each eye and with both eyes together 20/15. A +2.50D. sph. addition gave a near vision of J1 with an unusually good range. He obtained his glasses on April 11th, and resumed his work as an accountant.

Twelve weeks after operation, on April 24th, he returned because his left eye had been sore for two days and the vision in it had become blurred. Examination showed that the anterior chamber was entirely flat and vision reduced to 20/40. The eye was slightly congested. No leak could be discovered with fluorescein. Atropine was used and a dressing applied. By the following day the anterior chamber was restored. The next day it was lost again and minute leak was discovered in the 12-o'clock meridian. The area was cauterized with trichloracetic acid and a firm dressing was applied.

For about a week the anterior chamber remained normal but on May 7th it was flat again. The actual cautery was used without benefit. On May 10th, he was readmitted to the Memphis Eye and Ear Hospital and a conjunctival flap was dissected up from the limbus. The limbal wound was cauterized with actual cautery and then the flap drawn over it and fastened with heavy silk sutures. Following this the anterior chamber was restored and has so remained.

After about 10 days, the flap slid off but the eye remained highly congested. Intraocular pressure now rose to 35 mm. Hg, (Schiøtz) and there was considerable iritis. Eserine was used for a short time, but mydriatics were employed most of the time. The tension remained around 25 mm. Hg usually, occasionally rising into the 30s. The iritis continued in spite of the regular use of atropine, injections of foreign protein, and salicylates.

Complete physical and laboratory examinations and also X-ray studies of teeth, sinuses, and so forth were negative. On about August 1st, a whitish-looking membrane appeared in the anterior chamber just beneath

the apex of the wound. This growth enlarged very slowly.

The patient was referred for X-ray treatment and to date between 600R. and 700R. have been given. Apparently the epithelial ingrowth had become inhibited. The eye was less congested and less sensitive.

This case was unusual in that no complication developed until 12 weeks after cataract operation, when a leaking wound with loss of the anterior chamber developed. This was followed by irtis, secondary glaucoma, and finally by an epithelial ingrowth. It was felt that if the X-ray therapy failed to control the condition, further surgery might be attempted.

Berman locator brings success

Dr. Philip Meriweather Lewis reported a case in which the Berman locator proved of great value.

B. N., a colored man, aged 37 years, was struck in the right eye while using a hammer in the repair of some machinery. When seen the following day, there was a 2.5-mm. horizontal wound in the center of the cornea. There was a wound also in the lens, which was milky throughout. Vision was reduced to counting fingers. He was sent to the Memphis Eye and Ear Hospital for X-ray localization.

The report showed the foreign body to be just outside the sclera in the inferior nasal quadrant. The globe was of normal firmness, which suggested that the sclera had not been perforated. Application of the giant magnet to the cornea gave no response. An exposure was made of the sclera in the inferior nasal quadrant.

Application of the tip of the Berman locator to the sclera showed that the foreign body was within the eye. The greatest intensity of sound occurred when the tip was at a point in the 135-degree meridian, 11-mm. posterior to the limbus. An incision was made at this point, and 6-0 silk sutures were inserted when the incision was about two thirds through the sclera. After completing the scleral and choroid incision, application of the tip of the hand magnet to the wound immediately drew out the foreign body. It measured 2.5 by 1.2 by 0.5 mm. The scleral incision was closed and surface diathermy was applied to the wound and the immediate surrounding area. Convalescence was uneventful. The Berman instrument made the removal of this foreign body extremely easy in spite of a misleading X-ray report.

Directors: LAWRENCE T. POST, President; WILLIAM L. BENEDICT, Vice-President; WILLIAM A. MANN, Secretary and Treasurer; WILLIAM H. CRISP, FREDERICK C. CORDES, DERRICK VAIL.

Address original papers, other scientific communications including correspondence, also books for review to *Dr. Derrick Vail, 700 North Michigan Avenue, Chicago 11, Illinois*; Society Proceedings to *Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin.* Manuscripts should be *original copies*, typed in *double space*, with wide margins.

Exchange copies of medical journals should be sent to *Dr. F. Herbert Haessler, 324 East Wisconsin Avenue, Milwaukee 2, Wisconsin.*

Subscriptions, application for single copies, notices of changes of address, and communications with reference to advertising should be addressed to the *Manager of Subscriptions and Advertising, 664 North Michigan Avenue, Chicago 11, Illinois.* Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the *Manuscript Editor, Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin.* Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Ahnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

THIRTIETH ANNIVERSARY OF THE JOURNAL

With the issue for January, 1948, Series 3 of the AMERICAN JOURNAL OF OPHTHALMOLOGY entered its fourth decade. The changes in ophthalmology during this period can be culled from the JOURNAL's pages. The developments are recorded in many original articles, abstracts, and editorials.

Volume 1 of Series 3 witnessed the amalgamation in 1918 of six publications under the name of the AMERICAN JOURNAL OF OPHTHALMOLOGY. These journals with their chief editors and dates of founding were as follows:

The American Journal of Ophthalmology .....Adolf Alt, 1884

Annals of Ophthalmology .....James Pleasant Parker, 1891

The Ophthalmic Record .....Giles C. Savage, 1891

Anales de Oftalmologia .....M. Uribe-Troncoso, 1898

Ophthalmology .....Harry V. Wurdemann, 1904

Ophthalmic Year Book and Literature .....Edward Jackson, 1904-1911

Of these editors only our distinguished

confrere Dr. M. Uribe-Troncoso survives. He continues to contribute articles regularly to the JOURNAL as he does to ophthalmology as teacher and practitioner and our readers know that he edits our Pan-American page. His work on gonioscopy has been the most outstanding of anyone in that field.

On the editorial staff of Series 3, Volume 1, were: Adolf Alt, M. Uribe-Troncoso, Meyer Wiener, Casey A. Wood, Harry V. Wurdemann, Edward Jackson, and Clarence Loeb. The first issue was made up of 92 pages, the departments being not too different from those of the JOURNAL today—Original Papers, Abstracts, Society Proceedings, Editorials, Book Notices, News Items, Index of Ophthalmic Literature, and Digest of the Literature, the last under four headings: Methods of Diagnosis, Edward Jackson; General Therapeutics, William H. Crisp; Operations, M. Uribe-Troncoso; Refraction, Theodore B. Schneideman.

Appropriately enough, the first editorial was on the new JOURNAL by Edward Jackson who had the idea of the amalgamation of the six publications and was the first editor-in-chief and for many years the spirit and soul of the JOURNAL. The second editorial in the same issue was on advertising. Dr. Jackson was always strict as to the type and character of the advertising and set a standard for that. Many of the advertisers in the first issues have continued to utilize the JOURNAL through all the intervening years.

Among the contributors to the first issue was Thomas Hall Shastid who for many years wrote interestingly and forcefully on ophthalmic matters. His autobiography *Tramping to Failure* is a classic. In this first issue he wrote on "A Composite Ophthalmia Neonatorum Law." He stated in characteristic fashion "At all events, our present ophthalmia neonatorum laws, fragmentary and hastily constructed as they are, for the most part

'Play such fantastic tricks before high
Heaven
As make the angels weep.'"

He then proposed a new form of law.

Samuel D. Risley of prism fame discussed "The Rise and Progress of Ophthalmology in Philadelphia." It was he, I believe, who stated that myopia increases on the turnstile of astigmatism. David Wells, whose stereoscopic charts have been so much used, was writing from Boston about the stereoscope. Marcus Feingold, famous pathologist of New Orleans, had a paper on "Essential Atrophy of the Iris" with a beautiful colored illustration and excellent insert plates of a specimen.

We seem not to be much further now in our efforts at finding a satisfactory treatment for retinitis pigmentosa, as it was then universally called, than we were then. In the February, 1918, issue, E. L. Jones reported a series of cases of retinitis pigmentosa treated with thyroid extract, his paper being entitled "Relation of Retinitis Pigmentosa and Allied Conditions to the Ductless Glands." Today there are those who are treating this condition with liver extracts and placental injections. One wonders whether 30 years have added anything of value to the treatment of this disease.

Throughout this first year there are many papers that had to do with the war. In the July issue one of Jackson's ever-recurring articles on "Education for Ophthalmic Practice" is to be found. In this article he stressed the importance of establishing in each medical school "short courses in physiologic optics, ocular anatomy, and ocular pathology, and would bring these to the notice of every medical student as courses to be taken before seeking the clinical part of training for ophthalmic practice." In his last paragraph he suggested that the American Board of Ophthalmic Examinations should divide its examination into two parts giving "students who have been out of medical school one year or more an examination on ocular anatomy, the physiology of vision, geometric, experimental, and physiologic optics, and ocular pathology. Two or more

years later there could be given the examinations in the clinical subjects."

Orozimbo Netto's paper on "An Etiological Factor in Trachoma" is interesting as illustrating the diversity of thought on this subject at that time. He suggested that pediculus vestimenti might be an intermediary host and stated that "The best treatment known today for true trachoma is, undoubtedly, the excision of the trachoma tissue."

In an editorial in the September issue, Jackson wrote about "An Ophthalmic Adventurer—Julius Homberger." He was a German who came to New York in January, 1861. In July, 1862, he published the first number of a journal which he named "The American Journal of Ophthalmology." It was to be issued bimonthly. In the first volume of 256 pages all those authors mentioned were foreign except E. Williams of Cincinnati. Of the second volume only two issues apparently were published though the character of Volume I was good. Adolf Alt who started the second JOURNAL series apparently named his journal "The American Journal of Ophthalmology" without knowing of Homberger who had disappeared from professional view some 15 years earlier.

With January, 1919, the format of the editorial list was changed. Edward Jackson and Casey A. Wood were listed as editors while Alt, Wiener, Troncoso, Wurdemann, and Loeb were listed as associate editors. From 1918 to 1928, *The Ophthalmic Year Book* was published as a supplement to the AMERICAN JOURNAL OF OPHTHALMOLOGY. In 1918, this was Volume XIV of the *Ophthalmic Year Book*. The year book was begun and edited by Jackson and later by Crisp until 1926. After 1918, the year book was under the financial auspices of the JOURNAL and was published each year at a considerable monetary loss. However, the directors of the JOURNAL always considered the year book such a valuable contribution to ophthalmology that they continued to publish it until finally the burden became too great and for lack of other sponsors the year book was discontinued.

The spring of 1919 saw the sunrise for which all the world was waiting. This was reflected in the JOURNAL articles for that year. However, there were still later war articles published toward the end of 1919 and for several years thereafter. One of these on "The Control of Trachoma Among the Alien Labor Companies of the British and American Expeditionary Forces" was by George S. Derby, a senior ophthalmic consultant to the A.E.F. He, Alan Greenwood, and Nelson M. Black occupied important consultative positions with our forces overseas in this war and were continually to be found in one hospital or another striving to bring order out of the chaos that is inevitable whenever a peace-loving and peace-serving nation undertakes a world war.

In the issue of October, 1920, there is a biographical sketch of Adolf Alt, one of the original editors, who migrated from Germany to become an assistant to Herman Knapp in the New York Ophthalmic and Oral Institute, in 1875. In 1880, he moved to St. Louis. He was a distinguished ophthalmic pathologist and one of the founders and first president of the American Academy of Ophthalmology and Otolaryngology, and as previously noted founder of Series 2 of the AMERICAN JOURNAL OF OPHTHALMOLOGY.

The year 1922 saw the introduction of butyn, a drug still used by many, especially by those sensitive to pontocaine. However, pontocaine has largely replaced butyn for anesthesia of the globe when dilatation of the pupil is contraindicated.

Many pages in five successive issues in 1922 were devoted to a consideration of the proceedings of the International Congress held in Washington from April 25th to 28th. These were prepared by George E. de Schweinitz. Twenty-six years have elapsed since then and regrettably the Con-

gress has never returned to the United States. Many notable figures attended this convocation. The opportunity to meet them constituted one of the most important features of the congress for United States ophthalmologists.

In 1924 was published one of William C. Finnoff's famous papers on "Changes Found in Eyes of Rabbits Following Injection of Living Tubercle Bacilli into the Common Carotid Artery." It was a great loss to ophthalmology that one so gifted must die so young. An accompanying paper "Changes in Eyes of Rabbits Following Injection of Dead Tubercle Bacilli into Common Carotid Artery" appeared later in the year.

In 1926, John Evans published a preliminary report on retinal visual scotoma, the beginning of exact and beautiful studies that he has continued to make through the years. A comprehensive article appeared in July of the same year.

In 1928, M. H. Post made a first report on his studies on the sterilization of instruments. In 1928 also, S. Judd Beach began to write about the selection of test types for refraction. It is interesting to note how consistently ophthalmologists have maintained through the years their interest in and studies on subjects that once attracted them.

William H. Crisp replaced Edward Jackson as editor of the JOURNAL in 1928 and retained this position for three and a half years at which time he planned to be absent from the country for a while and so turned over the editorship to the writer. Dr. Crisp has always been interested in higher culture, having himself a remarkable knowledge of literature and languages with many of which he has conversational ability. The JOURNAL during his editorship gave evidence of his exactness as a student. One of his first articles while editor was on "The Literary Phase of Ophthalmology." Long before this he had popularized Jackson's cross cylinder by demonstrating its use and by writing clarifying articles on the subject.

Of historical interest in Volume 13 is the paper by W. H. Wilmer on "Some of the Early Eye and Ear Infirmaries in the United States and the Men Who Made Them."

At this point it might be interesting to JOURNAL readers to know something of the financial policy and history of the JOURNAL. Dr. Jackson, when he amalgamated the other periodicals with the AMERICAN JOURNAL OF OPHTHALMOLOGY, believed that the publication would prosper and represent the profession best if a large number of ophthalmologists rather than only a few had a financial interest in it. He, therefore, formed a stock company owned entirely by oculists who were encouraged to subscribe to one or more shares up to a limited number. Many eye physicians were interested and purchased stock which sold at $20 a share. This method of underwriting has remained throughout the years and from time to time when a few shares were offered for sale, the JOURNAL has purchased them and resold them to ophthalmologists. Jackson also established a policy of paying small dividends to stock holders and putting any excess profits back into the magazine to make it a better publication. A policy of paying for articles accepted for publication was followed for a few years, but then discontinued. The JOURNAL has been financially successful so that dividends were paid in all but two years which were in the depth of the depression.

When Dr. Crisp relinquished the editorship in 1931, Miss Emma Buss joined the staff as manuscript editor. She served efficiently and devotedly until her death, 15 years later. She gave unstintingly of herself to this work, having a fine mind and a splendid education, and was most helpful in the mechanics of editing.

For two or more decades, the leading figure in the world of ophthalmology was Ernst Fuchs of Vienna. His death, in 1930,

was memorialized in the January, 1931, issue of the JOURNAL by tributes from many of his former friends and students. From about 1870 until the first World War, Vienna was the Mecca of American ophthalmologists. From the early 1880s, Professor Fuchs's clinic was the most popular in the world. After World War I he brought his teachings to America, since Austria was no longer in a position to care for foreign ophthalmologists.

In July of 1931, the writer succeeded Dr. Crisp as editor of the JOURNAL. No radical changes took place since the new editor was in accord with the policies of his predecessors. Two years later, however, the editorial board underwent several changes. Clarence Loeb retired from the staff because of incapacitating illness which not long thereafter claimed his life. His loyal and long-time service with the JOURNAL was deeply missed. Rommel Hildreth, Park Lewis, and M. F. Weyman were added to the board. The death of the last named shortly thereafter robbed the profession of an extremely promising young man who had already been appointed associate professor of ophthalmology at the University of Southern California and departmental head in that institution.

In 1932, Otto Barkan described a procedure for the extraction of soft cataracts since widely associated with his name. In the September and October issues appeared articles on historical and experimental keratoplasty by Ramon Castroviejo which did much to popularize this operation. In the 16 intervening years many other articles on this subject have appeared in the JOURNAL, the technique and results continually improving.

Throughout the years distinguished foreign ophthalmologists have frequently contributed original papers to the JOURNAL. In 1933 alone were included such men as Lieut. Col. R. E. Wright of Madras; Ignacio Barraquere of Barcelona; R. Sondermann of Berlin; Carlos Charlin of Santiago, Chile; and T. Wassenaar of Pretoria, South Africa.

In the first issue for 1934, the leading article was on retinal detachment by Clifford B. Walker. Already well known for stressing the value of tiny test objects in taking fields of brain-tumor cases, he spent his later years in a meticulous study of retinal detachments, and was undoubtedly one of the most important figures in the development of the surgery of this condition. This was the first of many articles published by him in the JOURNAL on this subject.

The year, 1934, saw also a paper by George H. Stine on "A Method for Accurate Localization of Retinal Tears." This is probably the method most frequently followed to this day by ophthalmic surgeons in this operation.

In this volume we also find one of the many papers by that most able laboratory worker, Jonas S. Friedenwald, this one on "Retinal Vascular Dynamics." Throughout the years his alert mind has continued to explore new paths. His Jackson Memorial Lecture this year described his utilization of a new staining method for polysaccharides and mucoids that had been used for general pathology and applied by him to the eye. In his preliminary report it was obvious that a new field was opening in ocular physiology and pathology. His thesis on this subject will be published in a later issue of the JOURNAL.

In 1938 and 1939, a remarkable series of 12 lectures on motor anomalies by A. Bielschowsky appeared in the JOURNAL. These were considered so valuable that they were later published by Dartmouth College as a monograph and have served as a text for many students since then.

The editors have always had a keen interest in research and early made arrangements to publish the proceedings of the Association for Research in Ophthalmology. These papers have been a valuable addition to the JOURNAL and at the same time the JOURNAL's coöperation has been a real help

to the Society. Another effort sponsored by the JOURNAL has been the publication of the papers read at the joint meeting of ophthalmologists and orthoptic technicians in connection with the meeting of the American Academy of Ophthalmology and Otolaryngology each year.

In 1941 the writer, having served 10 years as editor, deemed it wise to pass this editorship on and suggested the name of Derrick Vail to the directors who appointed him editor-in-chief. One cannot praise too highly the efficient manner in which he has carried on since that time. He has been able to obtain the best papers and to increase both the size of the JOURNAL and the list of subscribers. This list is now well above 4,000, including many subscribers in foreign countries.

Before the first World War there were no ophthalmic publications equal to those of the Germans. For a time it appeared that these would be successfully revived, but the events preceding the second World War and the war itself obviously have reduced European ophthalmology to a very bad state. It now devolves, therefore, upon England and the United States to carry the torch for the world until such a time as our European brothers can again light their lamps for the benefit of us all.

BOOK REVIEWS

MODERN TRENDS IN OPHTHALMOLOGY. Edited by Arnold Sorsby. 2nd edition. Clothbound, 600 pages, 169 illustrations, 3 color plates. New York and London, Paul B. Hoeber, Inc., Medical Book Department of Harper & Brothers, 1947. Price, $12.50.

This book has provided an important part of the reviewer's technical summer reading. The intention had been to give it a rather brief examination since the first edition of seven years earlier was well known. But so much change has taken place in ophthalmology and general medicine during that period and the book contains such a large amount of this new material that it was found to be too interesting to hurry through.

The book is composed of 48 monographs on ophthalmic subjects of unusual interest. Many authors who have exceptional information about them have contributed the chapters. There are five main divisions: Physiology, Diagnostic Procedures, Pathology, Treatment, and Social Aspects.

Part of the first section will be unfamiliar to many ophthalmologists and the most difficult to read. If they will take the necessary time, however, they will find a rich reward. Even if the ophthalmologist is familiar with the basic principles, he will find much recent experimental work described that has materially changed the current thinking on the topic. Chapters that are particularly intriguing are those on the mucopolysaccharides and mucoids, and the one on variations and correlations of the optical components of the eye. F. P. Fischer has written a provocative chapter on senescence of the eye.

John Evans is always convincing when he writes about angioscotometry; so much so in this chapter that the reader may wonder why he has not spent more time on this technique. Probably the inhibiting factor is the very lack of time. This presentation forms a good antithesis to the following one on *ophthalmodynamometry* by Espildora-Luque, especially on the theories of glaucoma. Evans considers it possible to make a diagnosis of pregnancy in very early stages by angioscotometry.

It should be noted that each subject in the book is only briefly considered and not at all intended as a complete monograph on the subject. It considers only some point that has interested the author. The reader is in fact in danger of being carried away by the writer's enthusiasm until he reads further and finds, perchance, a contrary view

equally ably advocated by someone else!

A fine example of contrary viewpoints is that of the two adjoining chapters on focal infection, one by Woods and one by Berens; the former thinks it plays a very small part in uveal disease, whereas the latter contends that virulent coliform bacilli located in the throat and nose may be of serious import in many cases.

Ballantyne and Michaelson present a good discussion on "Affections of the Retinal Veins," and Wagener and Rucker on "Eye Changes in Blood Dyscrasias."

Stina Björk in writing on "Hypertensive Retinopathy" points out that many observers cannot concur completely with Bailliart and others in their conclusions regarding the relationship of retinal arterial hypertension and systemic arterial hypertension.

There are good chapters on X-ray and Grenz-ray treatment.

In another section Weekers states that 40-percent alcohol retroörbital injections are not used nearly often enough and overlooked in many conditions in which they are helpful.

All in all we have here a most instructive and entertaining book which will enable the ophthalmologist to keep up to date in his thinking.

Lawrence T. Post.

CHILDREN'S EYE NURSING. By James H. Doggart. London, Henry Kimpton, 1948. 144 pages, 93 illustrations including 13 in color, index. Price, 9 shillings, 6 pence.

This is a useful little manual of eye nursing in general, with particular mention of that pertaining to children. It contains a brief description of the anatomy of the human eye and adnexa and a discussion of its more usual afflictions and their nursing care based on a knowledge by the nurse of what the physician sees and does. This is a sound approach because the more the nurse knows and understands of ophthalmology the better is her professional attention.

One of the most useful chapters is that on instruments and dressings. It is generously illustrated with full-size cuts of the more common eye instruments. A description of their care and storage merits especial attention, for in many places the delicate tools of our trade are often cruelly manhandled.

It is too bad that the title implies that eye nursing for children is different from that for the adult. This is not so, as we all know. The use of the manual would not be quite so restricted either if the title were not. It is a good job and is recommended not only for the ophthalmic nurse but chiefly to those beginning that specialty.

Derrick Vail.

TRANSACTIONS OF THE SOCIÉTÉ FRANÇAISE D'OPHTHALMOLOGIE. Volume 60, 1947.

This volume contains the report of the scientific sessions from May 18, 1947, to May 22, 1947. Sixty-three papers and their discussions are presented.

The demonstration of Professor Bonnet's ophthalmoscopic atlas was one of the most important features in the symposium on fundus diseases. Toulant, Beuhamou, and Foissin report on an epidemic dacryoadenitis, characterized by the severeness of the general symptoms, the mildness of the local disease, a fall in the blood proteins, and a high eosinophylia. H. Pagès and J. Duguet describe brawny ectropion as a rare complication of Koch-Weeks conjunctivitis. Dejean and Gassene used a full-thickness postauricular, skin-hair flap in the reconstruction of a burned upper lid. F. Thiébauts, L. Guillaumats, and P. Bregeats present their study of relative hemianopia, with a new perimetric technique—the simultaneous examination of the nasal and temporal fields in one eye or the corresponding fields in in both eyes.

A. Busacca has a detailed paper on the lymph channels of the normal and diseased

conjunctiva made visible by the injection of Trypan blue. R. Nataf reports his studies on trachoma resumed after the war years.

Primary edema of the cornea was discussed by L. Paufique, H. Chavanne, and J. Prost. They studied, clinically and anatomically, eight cases of this rare and mysterious disease which they suggest should be treated by lamellar keratoplasty.

In the symposium on keratoplasty, an anatomic and clinical observation of a nonperforating graft is recorded by L. Paufique and Guy Offret. The graft survived.

Jean Sédan and G. Farnarier discuss the spontaneous clearing of a traumatic cataract. Jean Sédan and Simone Sédan-Bauby add some details to the previously published description of the micropuncture of the taut capsule of a cataractous lens.

The experimental transplantation of vitreous from one eye of a rabbit to the other was successfully accomplished in a certain percentage of cases under a painstaking technique by John D. Blum and H. M. Katzin who emphasize the surprising lack of inflammatory reaction of the uvea after this operation.

Diathermy coagulation of wounds in the ciliary region is recommended by Thomas, Cordier, and Michel in preference to other therapy of this dangerous type of injury.

A valuable contribution to the diagnosis of human toxoplasmosis and a detailed description of the eye lesions are given by Franceschetti and Bamatter.

Calmettes, Deodati, and Tabarly suggest repeated small blood transfusions in recurrent retinal and vitreous hemorrhages of young adults. E. Redslob suggests tonoscopic examination in the differential diagnosis of real ophthalmic migraine which is characterized by a retinal hypotension. R. Weekers reports on his results in the treatment of hypertensive uveitis with nonperforating cyclodiathermy. Kalt discusses X-ray treatment in retinal blastoma which he recommends be continued through several years.

The possible hypersensitivity of the carotid and cardio-aortic sinus and the danger of a glaucoma attack in the sudden fall of blood pressure are mentioned by Streiff. M. Rauher describes the late and immediate effects of novocaine on normal and pathologic retinal circulation. Jean Gallois emphasizes the importance of capillary dilatation in the evaluation of intraocular diseases and explains the effect on the retinal elements.

A very original paper by R. Weekers deals with the exploration of visual function by testing the critical frequency of fusion—the smallest amount of illumination per second under which a discontinuous stimulus gives a continuous visual sensation. The measurement of the critical frequency of fusion is an extremely sensitive method and sometimes reveals defects which the campimeter does not show.

Other papers of interest include a study on visual disturbances and retinal changes caused by anoxemia in aviators (P. Dumont, J. P. Bailliart, A. Mercier, and J. Duguet) and a study of the cells in the aqueous (Thomas Verrey).

In another group of essays various aspects of intraocular chemotherapy are described. L. Alearts records the circulation of sulfonamides in the aqueous; A. Dubois-Poulsen and H. Miller observe the therapeutic effect of penicillin injections into the anterior chamber; and W. I. Kapuscinsky recommends the puncture of the anterior chamber as a most powerful vasodilatator of the retina in toxic neuritis and optic atrophy.

G. Renard and P. Bregeat discuss their first eight cases of retinitis pigmentosa as treated with subconjunctival implants of placental tissue. They could not notice any change in the appearance of the fundus. Visual acuity was slightly improved in three cases; visual fields slightly enlarged in four; adaptation was subjectively improved in seven.

Many papers carry a detailed biography.

Alice R. Deutsch.

CORRESPONDENCE

Ophthalmic equipment needed*

Editor,

American Journal of Ophthalmology:

This is a great work and the professorship of ophthalmology takes me half time during the year. The rest of the time I am in Mungali. The department is going well but I do need 25 used and fixed-up ophthalmoscopes for my medical students. Do you suppose there are in the profession even more than that good ophthalmoscopes not being used?

So great is the demand and so scarce is the supply that it would be a great lift to ophthalmology in India if we could have here old, used, but good equipment—slit-lamp microscopes, ophthalmometers, instruments of all kinds, charts for examining eyes, just everything that an ophthalmologist needs.

We are doing 1,500 cataracts a year in Mungali and Vellore now and when we do the 10,000 we want to do we will have more work for our fine young, and older surgeons, too.

(Signed) Victor C. Rambo,
Vellore, South India.

Tonometric readings

Editor,

American Journal of Ophthalmology:

If one follows the recent literature relating to the early recognition of glaucoma, one gains the impression that many physicians attach too much importance to small differences in the readings obtained by the use of the tonometer. While efforts have been directed toward enlarging the scale of the tonometer, so that readings can be made with greater accuracy, the inherent sensitivity of the instrument remains the same.

The application of the tonometer in diagnosis is limited by two important factors: (1) The technique of carrying out the measurement is subject to unavoidable errors arising from the personal equations of both patient and doctor, as well as from the nature of the instrument itself; (2) there has been recognized a wide variation in the rigidity and thickness of the coats of the normal eyeball.

These factors, which affect the ability of the tonometer to indent the cornea irrespective of the intraocular pressure, have been analyzed by Friedenwald (American Journal of Ophthalmology, 20:985, 1937) in an attempt to arrive at a more accurate estimate of the intraocular pressure.

From an historical point of view, it is interesting to note that Schiøtz, himself, was aware that the tonometric reading was influenced by factors other than the intraocular pressure. The following is quoted from his article in the *British Journal of Ophthalmology*, 9:150 (April) 1925:

"We may safely assume that for each degree of pressure the maximum and minimum deflections in living eyes will be about the same as we have found on dead eyes. . . . With 29 mm. Hg one may have, in different eyes, deflections varying from 2.2 mm. to 4 mm.; with 15 mm. Hg one may have deflections from 6.2 right up to 9.4 mm. Consequently with a deflection of 3 mm. (5.5. gm. weight), the pressure will as a rule no doubt be about 29 mm. Hg, but that deflection might be properly referable to the minimum graph and to an intraocular pressure of 26 mm. Hg, or to the maximum graph and a pressure of 33 mm. Hg. *This should absolutely be borne in mind when using a tonometer: the deflection of the pointer does not indicate a precise pressure but a pressure-range, which for the 5.5 gm. weight is about 6 to 8 mm., Hg, for the 7.5 gm. weight 8 to 10 mm. Hg, for the 10 gm. weight about 13 mm. Hg,* and for the 15 gm. weight about 15 mm. Hg, nor can it be otherwise when we take into consideration

---

*Editor's note: This request comes from the Union Christian Medical College at Vellore, South India. The establishment of this college represents one of the most significant developments in the history of missionary enterprise. Actively coöperating in the work of this medical college are 38 mission boards from all over the world and their aim is to establish a medical college to serve all India.

the individual peculiarities in the size of the eye and in the thickness and elasticity of its wall."

From the foregoing, it appears that even if one assumes with Schiøtz that 30 mm. Hg represents the average upper limit of normal tension, one is never certain whether this normal limit may be applied to the eye in question. Thus, a tension of 30 mm. Hg obtained with a 7.5 gm. weight may represent as much as 5 mm. above normal for one eye and as much as 5 mm. below the upper limit of normal in another. Any criteria based on the use of the tonometer must be evaluated in the light of such observations.

New York.

PSYCHSOMATIC INTERRELATIONSHIPS

Editor,
American Journal of Ophthalmology:

In his interesting paper on "Psychosomatic interrelationships in ophthalmology" (Am. J. Ophth., 31:1241 (Oct.) 1948), Dr. Harrington writes: "The prescription of a pair of glasses, no matter what their dioptic power, may result in immediate relief of eyestrain, headache, blurring of vision and the like. Without a true analysis of the underlying cause and its treatment by psychotherapy, however, no more than a transient improvement, at best, can be expected."

One wonders if this is not riding the psychosomatic theory too hard. Every ophthalmologist has daily experience with refraction cases in which the prescription of glasses causes permanent, not transient, elimination of asthenopia or deficient vision or both. That the correction of the refractive error eliminates the trouble caused by the refractive error is a self-evident truth.

Perhaps Dr. Harrington means that it is the emotional conflicts that cause the refractive errors in the first place.

In that case, he should furnish proof that this is true. It is probably true in certain selected cases, but so far as I know, exact data are lacking. The claim is a familiar one. The late Dr. Bates, for example, stated dogmatically that "myopia" results when the patient is telling a falsehood. It is difficult to understand how lying can affect axial myopia even if one disputes established theories of accommodation!

Certainly, the psychosomatic theory offers a fruitful approach. One feels it can be most effective when it is limited to selected cases that are difficult to explain on a strictly organic basis.

(Signed) Philip Pollack, New York.

ABSTRACT DEPARTMENT

EDITED BY DR. F. HERBERT HAESSLER

Abstracts are classified under the divisions listed below. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

1. Anatomy, embryology, and comparative ophthalmology
2. General pathology, bacteriology, immunology
3. Vegetative physiology, biochemistry, pharmacology, toxicology
4. Physiologic optics, refraction, color vision
5. Diagnosis and therapy
6. Ocular motility
7. Conjunctiva, cornea, sclera
8. Uvea, sympathetic disease, aqueous
9. Glaucoma and ocular tension
10. Crystalline lens
11. Retina and vitreous
12. Optic nerve and chiasm
13. Neuro-ophthalmology
14. Eyeball, orbit, sinuses
15. Eyelids, lacrimal apparatus
16. Tumors
17. Injuries
18. Systemic disease and parasites
19. Congenital deformities, heredity
20. Hygiene, sociology, education, and history

CONJUNCTIVA, CORNEA, SCLERA

Bietti, G. B. and Pasca, G. **Research on the activity of streptomycin and its use on the inclusion bodies of trachoma in the conjunctiva.** Boll. d. Soc. ital. di biologia sperimentale. 24:82-85, Jan., 1948.

Fourteen patients with trachoma were treated with streptomycin and penicillin. Streptomycin has no advantage over penicillin. Improvement was slight and late. I. E. Gaynon.

Bietti, G. B., and Pasca, G. **Use of paraminobenzoic acid in trachoma.** Rev. internat. trachome. 25, Jan., 1948.

In eight cases of acute trachoma and six of chronic trachoma treated with 25-percent paraminobenzoic acid drops were given every two hours for ten days. Two patients were also given the same drug orally. There was no change in the number of inclusion bodies found. After the use of 0.1-percent sulfathiazole ointment the microscopic manifestations of trachoma disappeared. I. E. Gaynon.

Glees, M. **Clinical picture of smoke damage to the eye.** Klin. Monatsbl. f. Augenh. 113:43-44, 1948.

This short article discusses the various grades of conjunctival and corneal inflammation after smoke damage. The most malignant corneal lesions were seen in those in whom anaesthetic drops or ointments had been used.

Max Hirschfelder.

Harms, H. **The technique of penetrating corneal transplantation.** Klin. Monatsbl. f. Augenh. 113:59-64, 1948.

Following the idea of Vannas the author uses condom rubber of the size of a cornea to hold the transplant in place. The rubber is anchored by sutures in the episclera. A manual trephine is preferred to the motor driven type, as it permits more precise control. In order to obtain discs of equal size the pressure should be approximately the same in the donor and in the recipient eye. The danger of injuring the lens and iris is avoided in the following way. The trephine is rotated until aqueous is lost. Instead of completing the incision with scissors rubber is introduced into the anterior chamber as a protection to the underlying structures. The completion of the circular penetration is then continued with the hand trephine which will not penetrate the rubber in the

anterior chamber. The rubber is then removed through the completed trephine hole. The rubber is sterilized by a two-minute suspension in ether and in alcohol solutions ranging from 96 down to 15 percent. (References.) Max Hirschfelder.

Hartman, K. **Ectogenous conjunctival bovine tuberculosis and its treatment by electrocoagulation.** Klin. Monatsbl. f. Augenh., 113:20-28, 1948.

Infection in a young girl who had handled a dead rabbit is described. The patient exhibited papillary, partially ulcerated granulations of the conjunctiva of the upper lid with severe swelling of the parotid, submaxillary and regional glands. Laboratory tests showed bovine tuberculosis and one excised gland showed caseous necrosis. The persistent conjunctival granulations were removed by electrocoagulation in six sittings. The literature of the Parinaud syndrome is discussed briefly and the author feels that the clinical diagnosis of Parinaud's disease should be superseded by more specific etiologic terms. (References.)

Max Hirschfelder.

Maschler, J. **A case of pyocyaneus ring abscess of the cornea treated with streptomycin.** Brit. J. Ophth. 32:426-428, July, 1948.

A foreign body imbedded in the cornea of a 15-year-old boy was removed after two days. Three days later there was an extensive abscess in the cornea accompanied by hypopyon. Culture revealed B. pyocyaneus. He was immediately given 100,000 units of penicillin. It was injected under the conjunctiva and dropped into the anterior chamber after paracentesis. Heat, atropine and sulphadiazine were also prescribed. After a few hours streptomycin was instilled into the eye hourly, given intramuscularly every three hours and injected under the conjunctiva once, a total of one gram daily. During one paracentesis it was dropped into the anterior chamber (2,500 units in 2 drops). A broad Saemisch section was done and after three days the whole process regressed completely. After a few days an intense secondary glaucoma occurred and was relieved by a broad basal iridectomy. The central corneal area remained moderately opaque. Morris Kaplan.

Paton, R. T., McLean, J. M., Castroviejo, R., Maumenee, A. E., Kornblueth, W., Owens, W. C., and Woods, A. C. **Symposium: corneal transplantation.** Tr. Am. Acad. Ophth. pp. 312-353, March-April, 1948.

Paton discusses the selection of cases. A patient with reduced vision as a result of scarred cornea, but well adjusted and self supported, might better be left alone even though the corrected visual acuity is below 20/200. Highly nervous patients and those who are poorly adjusted emotionally make especially poor candidates for this type of surgery. Corneal grafting is done in much younger patients than cataract surgery, and it is well to remember that failure in them leads to more serious consequences from an emotional and economic point of view. No eye with scarred cornea should be operated on if iridectomy would bring about an improvement of vision. The most favorable cases are those in which there is a central nebulous opacity in an otherwise normal eye. There must be no active corneal disease, no infection of conjunctiva, cornea, or uvea, no increased tension, and no vascularization of the cornea. Blood staining of the cornea and conical cornea are favorable lesions, but in conical cornea it is not advisable to graft if the vision can be corrected to 20/200 even with a contact glass. Most cases of corneal dystrophy are not favorable for corneal transplantation. Calcareous degeneration, if it involves the entire cornea and full thickness, should not be operated on, but

if it is bandshaped with some clear corneal tissue in the periphery, transplantation should be attempted. Densely scarred corneas from powder burns do not do well. In general tattooing and corneal transplantation do badly in a highly vascularized cornea. There is perhaps no more favorable treatment of descemetocele than corneal transplantation.

McLean describes the process. Local anesthesia supplemented by akinesia and retrobulbar block is preferred. Donor eyes should be enucleated within six houfs after death, and preserved at 4 degrees C. in a sealed container having a saturated water vapor atmosphere. Both the square and circular types of transplant operations are described and illustrated. Beveling of the edges of the graft on the recipient cornea is not necessary. Present methods are all variations of the overlying suture to hold the graft in place. The shape of the graft is not of great importance. The high-speed mechanical trephine is the best means of cutting a true-edged graft. When cutting a graft by hand it is easier to make a square one. The operation can be mastered by any competent intraocular surgeon, but it should not be attempted by one who has not had considerable experience in developing his technique through many animal grafts.

Castroviejo describes complications that may occur during the operation and in the period of postoperative recovery. Partial detachment may be resutured, though usually unsuccessfully. If necessary, iris hernias should be excised about the third week and synechiae, the second week. Infection is best combatted with subconjunctival penicillin, streptomycin, and sulfadiazine. In complicating glaucomas, miotics, heat, and, if necessary, sclerectomy are advised. Excessive vascularization is best treated about the fourth week with 1,500 r. of radiation. Excessive and degenerative inflammations may justify the removal of focal infective process with or without intravenous injections of amino acids. Excessive edema may be reduced with 15-percent hypertonic sodium chloride jelly applied 3-6 times daily. Excessive protrusion of the implant is best treated with a properly applied pressure bandage.

In a section on physiopathology Maumenee and Kornblueth describe their experiments which were designed to elucidate the process of regeneration. The wound is closed at first by a fibrin clot, and later by fibroblasts which form fibrous tissue between the graft and the adjacent cornea. The epithelium is replaced by a migration of epithelium from the recipient cornea. The endothelium may be replaced from uninjured cells of the graft, or by migration of cells from the recipient cornea. The majority of the stromal cells continue to live in the graft and do not show massive degeneration or replacement at any time. They are supplemented to a limited extent by newformed keratoblasts from the macrophages of the recipient cornea.

Owen presents a statistical analysis of the results of 417 corneal transplant operations. The graft remained clear in 36.5 percent of the cases. The best results were obtained in keratoconus, hereditary dystrophy, interstitial keratitis and nonspecific inflammatory scars. No grafts remained clear in cases of Fuchs's dystrophy. The visual results after corneal transplantation in patients with preoperative vision of 20/100 do not warrant the risk of operation. Chas. A. Bahn.

Pines, N. **Denig's operation for trachomatous pannus.** Brit. J. Ophth. 32:385-394, July, 1948.

In this operation, mucosa of the lip is substituted for the scarred conjunctival mucosa. Under local anesthesia the bulbar conjunctiva is cut at the limbus to make a wound one and one half times as

long as the width of the pannus. It is important that this section go down to the episclera. All tissues are removed and the episclera is layed bare. While the assistant is securing hemostasis with hot saline sponges, a special forceps is applied to the lip and a section of the mucosa is cut out slightly longer and wider than the conjunctival wound. This graft is dropped in saline solution and the lip wound closed with one uninterrupted suture. The graft is laid out on a piece of glass and all the fat removed from it after which it is laid into the conjunctival wound with the mucosal side up and stitched with fine silk on three sides. The corneal side remains free. After five days the sutures are removed. At that time the graft will be pink and somewhat edematous if the operation has been successful; it will be white and freely movable if it has not.

The improvement in the eye is usually striking. However, the operation is applicable only in the third and fourth stages of the disease. There is a difference of opinion as to what brings about the improvement. Some observers believe that the peritomy alone is sufficient while others feel that the new tissue is a mechanical obstruction to the progress of the disease. The author presents four case reports. Morris Kaplan.

Rizk, K. **A case of keratomalacia cured by penicillin and vitamin A.** Brit. J. Ophth. 32:416-419, July, 1948.

A 2-year-old infant developed very severe keratomalacia of both eyes after a brief fever. Both corneas were almost completely opaque, bulged markedly and were covered by deep ulcers. There were few signs of inflammation and the baby seemed to be in no pain. The disease is primarily an avitaminosis A and is not ordinarily considered to be an infectious process. However, penicillin instillations and penicillin in wax were given in large doses. The opacities and the ulcers began to heal almost instantly although the epithelium was slow to regenerate. As soon as vitamin A was given healing progressed rapidly and completely. Dense leucomas remained only in small central areas. Both corneas resumed their normal shapes. Morris Kaplan.

Sjøgren, Henrik. **Keratoconjunctivitis sicca and chronic polyarthritis.** Acta Med. Scandinav. 130:484-488, 1948.

The author quotes Stenstam's statistics on the occurrence of this ocular condition to show that it exists in 10.5 percent of the cases of primary chronic arthritis. Sjøgren in his studies found that 93 percent of his cases occurred in males; Stenstam found the disease equally divided among the two sexes, yet further along in the article Stenstam is said to have found the severe form of keratoconjunctivitis sicca to be much more prevalent in women. Gifford in 1943 was said to have found one man to eleven women affected by the severe form. The author feels that the diagnosis of a mild case is rather difficult especially since Schirman himself says that his tear-function test is only a "very rough method," one which has never been standardized. As in the Gifford report, Sjøgren, too, found that in 40 percent of his pronounced cases no arthritis was present. The cause of this disease is unknown but two factors are worthy of consideration: one, infection, and the other, endocrine disfunction.

Francis M. Crage.

Stephenson, R. W. **Phlyctenular keratoconjuntivitis treated with penicillin.** Lancet 2:144-145, July 24, 1948.

The author reports a case of phlyctenular keratitis caused by an allergic reaction to staphylococcus. Response to penicillin therapy was good. I. E. Gaynon.

Swan, K. C., Emmens, T. H., and Christensen, L. **Experiences with tumors**

of the limbus. Tr. Am. Acad. Ophth. pp. 458-469, May-June, 1948.

The diagnostic differences of unusual limbal neoplasms are discussed. Benign leukoplakic lesions are nonvascular and carcinomatous lesions contain new or enlarged blood vessels. The transition to malignancy may therefore be observed by the appearance of new blood vessels. Lymphangiomas of the limbus tend to grow steadily. They do not metastasize but are locally invasive and destructive. They should be completely removed in the earliest possible stage. Simple lymph cysts tend to enlarge especially if they are near the palpebral fissure, and should be excised and not incised. Malignant melanotic tumors commonly arise from precancerous melanomas rather than nevi. Extensive surgical procedures are imperative. Granulomatous lesions may contain foreign bodies. It should be explained to the patient that the excision of lipodermoidal tumors frequently leaves extensive scar tissue. In the removal of limbal lesions a standard laboratory stereoscopic dissecting microscope is preferred. Stretching of Tenon's capsule may reduce or eliminate the need for mucous membrane grafts. Chas. A. Bahn.

Velhagen, K. **The type of vascularization in the differential diagnosis and clinical picture of some corneal diseases.** Klin. Monatsbl. f. Augenh. 113:28-36, 1948.

The differential diagnosis of corneal inflammations leading to deep vascularization is presented. The vessels take a straight course to the corneal center in luetic parenchymatous keratitis and do not show anastomosis. In the so-called sclerosing keratitis, which is usually caused by tuberculous scleritis, deep vessels enter the cornea for a short course, but instead of proceeding towards the corneal center they either form arcs or run straight through the peripheral parts of the cornea. Interstitial keratitis due to tuberculosis has very irregular and anastomosing vessels without a definite direction. They often surround grayish nodules in the cornea like a net. Rosacea keratitis is characterized by single branches or very small groups of vessels which often appear in the lid aperture. Frequently one finds small subepithelial or ulcerated infiltrates at the end of these vessels and some vessels may overshoot the location of the infiltrate. (4 figures, references.) Max Hirschfelder.

Venco, L. and Morone, G. **Some notes on the pathologic anatomy of grafted human cornea after keratoplasty.** Ann. di ottal. e clin. ocul. 73:221-246, April, 1947.

Histologic examination was made of six corneal transplants removed because of loss of transparency or for other cause from seventy days to one year after grafting. Dominant in the histologic picture was the edema affecting all layers. The epithelium was found to be markedly edematous from imbibition of fluid. Bowman's membrane was absent in two but was preserved in four cases. Since this membrane lacks regenerative power, its preservation points to the survival of the original membrane in the graft. In four cases the stroma showed cellular infiltration and new formation of capillaries; the lamellae were markedly dissociated and irregularly arranged; in two cases the stroma had undergone fibrillar transformation. Descemet's membrane was broken, detached, and rumpled, but was absent in only one case. In every case the endothelium was missing, probably because of handling in preparation of the specimens and because of involutional processes.

No one scheme was found sufficient to interpret the histologic processes observed. Venco and Morone believe they can distinguish four different possibilities.

1. A total transformation, in which the

graft is replaced by fibrous tissue. This occurs especially when the postoperative course is disturbed by such complications as infection, glaucoma, adhesion of iris to graft, and extensive vascularization and infiltration.

2. A subtotal transformation, in which the graft is only partially replaced by fibrous tissue. This occurs especially when the surrounding corneal tissue of the host is leukomatous. Presumably the leukomatous tissue lacks the vitality needed to cause complete transformation. Some of the original elements of the graft are found to persist, but not without losing their normal characteristics.

3. A partial transformation, in which localized opacities form in certain sectors of the graft and other parts remain transparent. An injury to Descemet's membrane in making the graft may result in poor union and thus occasion a localized organization of the stroma. Irregular edges or improper placement of the graft may cause the failure of normal metabolic relations to be established between host and graft at all points of contact. The part of the graft which will suffer most is that which is in contact with leukomatous or other abnormal tissue in the host.

4. No transformation of the tissue of the graft, which remains transparent throughout. This ideal result may be achieved when the postoperative course is perfectly quiet, without any kind of untoward reaction. In such cases the cicatricial ring between graft and host is frequently so fine as to be almost invisible, and there is reason to believe that a great part of the original tissue survives, especially the fibrillar framework.

Wolffersdorff, v. H. **Comparative studies of the course, treatment and epidemiology of epidemic keratoconjunctivitis in Saxony during 1941 and 1944.** Klin. Monatsbl. f. Augenh. 113:36-43, 1948.

The author gives a detailed clinical picture of epidemic keratoconjunctivitis as it appeared in Glauchau, Saxony, during two epidemics in the early forties. He presents a statistical analysis of an equal number of patients (322) during both epidemics. In 28 percent of the patients there had been major or minor trauma. The 37 patients operated on for cataract showed symptoms of the disease, but did not suffer serious consequences. In addition to 10-percent albucid solution and vitamin A ointment the author used X-ray irradiation, given in doses of 5 to 10 percent HED at 8 to 10-day intervals up to six doses and injections of 10 to 15 cc. own blood intramuscularly. He believes that injections of blood of convalescents properly typed for blood groups should be further investigated.

UVEA, SYMPATHETIC DISEASE, AQUEOUS

Bernstein, M. E. and Burks, B. S. **A note on iris rim color and width.** J. Heredity. 39:93, March, 1948.

Rim color of the iris falls into nine classes: two shades of blue, six shades of gray and one of very dark. In 78 percent of the people studied, the color of the main part of the iris was the same as that of the rim. If one parent had a narrow rim, the incidence of the narrow rim in the offspring was increased.

I. E. Gaynon.

Braun, R. **Tuberculosis and focal infection as causes of iridocyclitis.** Klin. Monatsbl. f. Augenh. 113:9-20, 1948.

It is pointed out that the importance of tuberculosis as cause of acute and chronic

iritis has been overemphasized in the German literature. The various pertinent clinical and laboratory findings as well as animal experiments are critically discussed. The proof for a hematogenous spread of tuberculosis to the eye is lacking except in the case of miliary tubercles. Much points to the correctness of the American idea of focal infection. Iritis, rheumatism and arthritis may be the result of the sensitization of mesenchym tissues and an allergic response to the primary focus. This focus can be in the tonsils, teeth, gallbladder, pelvic organs and, in some cases, can well be a tuberculous hilus gland. Removal of the focus will not necessarily stop the allergic reaction of the sensitized tissue immediately. Climatic treatment, irradiation, treatment with heavy metals and, perhaps, salicylic acid are helpful in bringing the sensitized tissues back to normal.

Max Hirschfelder.

Gilbert, W. **Early stages of ophthalmia lenta with remarks on the etiology of this disease.** Klin. Monatsbl. f. Augenh. 113: 1-8, 1948.

Ophthalmia lenta is a most severe chronic eye disease which begins with a recurrent uveitis, but finally affects retina, vitreous and optic nerve. It is always bilateral and is part of a syndrome which includes aphthous stomatitis and ulcerations of the genital organs, particularily of the scrotum. Changes in the skin have the character of an erythema nodosum. Eye symptoms may be so slight in the beginning that the dermatologist is likely to overlook or disregard them. Later, the recurrent severe hypopyon iritis can completely dominate the picture. The author refers to a somewhat similar but much more frequent ophthalmia in horses. He adds two cases to the literature on the subject and expresses the opinion that the syndrome is the allergic response to an infection, possibly by a virus. (References.)

Max Hirschfelder.

Gorduren, S. **Operative treatment of five cases of iridodialysis.** Brit. J. Ophth. 32:429-435, July, 1948.

Traumatic iridodialysis is not uncommon. It causes cosmetic and functional defects and should be treated as early as possible. The symptoms most complained of are reduced vision, dazzling, and monocular diplopia. Since 1917 the Golowin operation has been most employed and has served quite well. After local anesthesia a keratome incision is made just on the level of the iris root and parallel to its anterior surface. The knife is withdrawn slowly and the iris is allowed to protrude with the aqueous outflow. If the iris does not appear, it is pulled out with an iris hook. With two spatulas the iris is made to rest evenly in the wound and after the instillation of atropine, both eyes are dressed. The patients sit up after the first day, are out of bed the third day and resume work on the seventh day. *Morris Kaplan.*

Hart, W. W. **Sympathetic ophthalmia. Report of a case.** New Orleans M. and S. J. 101:85-87, August, 1948.

The clinical history is presented of a 48 year old negro woman in whom sympathetic ophthalmia developed 57 days after a penetrating injury. The inciting eye was enucleated five days later. The sympathizing eye smoldered for another four months and healed with a visual acuity of 20/120. The data presented throw no new light on cause, pathogenesis or treatment. F. H. Haessler.

Illingsworth, R. S., and Wright, T.

Tubercles of the choroid. Brit. M. J. pp. 365-368, August 21, 1948.

The authors report their observation on choroidal tubercles in 25 of 42 cases of miliary tuberculosis because of their probable prognostic value, and to emphasize their importance in diagnosis. Choroidal lesions establish a diagnosis before a radiograph of the chest or a lumbar puncture has been performed.

The natural history of the choroidal tubercle is described. As time passes, the margin of the tubercle becomes more definite, the tubercle enlarges, the center becomes paler, and the tubercle and the surrounding area become stippled with pigment. In the final stage there is a parchment-white scar with heavy surrounding pigmentation and paling of the near-by choroid.

It is suggested that further observation may well show that the changes described are of prognostic value. Of those cases (eight in number) in which in spite of prolonged streptomycin treatment the tubercles failed to progress beyond the early intermediate stage, death has occurred in five and the remaining three are doing badly. All the cases in which the tubercle progressed to the parchment-white stage without the appearance of any tubercles in earlier stages were apparently cured. (40 references, 6 figures on colored plate.) F. H. Haessler.

Kapuscinski, W. J. **Tuberculosis and focal infection in diseases of the mesenchymal tissues of the eye.** Arch. d'opht. 8:238-263, 1948.

Kapuscinski reviews the subject of the pathogenesis of uveitis and discusses in detail the concept, attributed to German authors, according to which the majority of uveal inflammations are of tuberculous origin. He concludes that histopathologic, bacteriologic, clinical, and therapeutic data now available do not substantiate these early claims made for tuberculosis but, on the contrary, tend to give to focal infection the major role in pathogenesis. He supports the view that the uveal tissue is sensitized so that it reacts to antigens released from a distant focus. He mentions the diagnostic value of intravenous injections of typhoid vaccine; a tuberculous infection would tend to be aggravated whereas one due to focal infection would usually improve. Acceleration of the sedimentation rate accompanied by an exacerbation of the uveitis after typhoid vaccine injection would suggest tuberculosis, whereas an acceleration of the sedimentation rate accompanied by improvement in the local focus would suggest focal infection. There is no acceleration of the sedimentation rate when there is no systemic infection.

The author describes 12 cases of which two were undoubtedly tuberculous. The others were a result of focal infection, for the most part dental. He does not support the theory of organotropic bacteria (Rosenow) and concludes that the allergic theory, while more satisfying, does not cover all cases. He concludes by stating that there are only three causes of intrinsic inflammation of the mesenchymal tissues of the eye: (1) syphilis (about 15 percent), (2) tuberculosis (about 3 to 5 percent), and (3) the focal infections (streptococcic, staphylococcic, gonococcic, and others).

Phillips Thygeson.

Lasky, M. A. **Essential progressive atrophy of the iris.** Am. J. Ophth. 31: 1131-1134, Sept., 1948. (3 figures.)

Marquez, M. **Ocular hypertension in glaucoma.** Ann. d'ocul. 181:351-361, June, 1948.

Glaucoma and ocular hypertension are not synonymous. That hypertension is only one of the variable symptoms of glaucoma has been shown by the numerous cases of glaucoma without hyperten-

sion which have been reported in ophthalmic literature. The glaucomatous excavation is absolutely independent of ocular tension, and peripheral as well as central visual defects are essentially due to retrobulbar vascular degeneration. Basically, primary glaucoma is always chronic. Primary glaucoma may be controlled but never cured. Among the newer therapeutic agents now under investigation are nicotinic acid and rutin. The use of the former is based on a minimal elective vasodilatation and of the latter, on possible reduction of capillary fragility.

Moutinho, H., and De Moura, S. **Meningococcic iridochoroiditis (an exclusively ocular form of meningococcic infection).** Ann. di ottal. e clin. ocul. 73: 311-320, May, 1947.

Metastatic iridochoroiditis is a well-known complication of epidemic cerebrospinal meningitis, but the possibility of meningococcic iridochoroiditis without manifest meningitis has hardly been recognized. Moutinho and De Moura present eight cases of unilateral metastatic iridochoroiditis occurring at the height of an epidemic of meningococcic meningitis in children who had no meningitis and were otherwise quite well. The ages of the patients varied from five months to three years. In the evolution of the disease three characteristic stages were recognized: 1. mild general and meningitic symptoms, lasting less than 24 hours; 2. an interval of 2 to 4 days when everything seemed normal; 3. obvious iridochoroiditis. In three patients lumber puncture was done, and in two of these gram-negative diplococci with the morphologic characteristics of the meningococcus were found. The spinal fluid was otherwise normal. An ocular puncture was done in one eye, and the fluid showed diplococci with the same characteristics. The endophthalmitis was severe, with purulent exudate and eventual cicatricial contraction tending to phthisis bulbi.

Harry K. Messenger.

Radnot, Magda. **Contribution to data on sight disturbances caused by proliferation of pigment epithelium.** Brit. J. Ophth. 32:423-426, July, 1948.

In an 82-year-old woman, who had had an intracapsular cataract extraction with a round pupil several years before, the vision was limited to the counting of fingers and the entire pupil and coloboma was filled with a dark brown film. Slit-lamp examination revealed a solid sheet of pigment on the anterior surface of the vitreous. Presumably the pigment epithelium of the iris had been injured in the operation and had proliferated until it covered the whole anterior surface of the vitreous.

Morris Kaplan.

Sautter, H. **Some interesting findings on the iris.** Klin. Monatsbl. f. Augenh. 113:44-51, 1948.

Two malignant melanomas were cured by iridectomy. A third case is one of a metastatic carcinoma carried from the testis to the anterior uveal tract through the anterior ciliary vessels. Metastasis through the anterior ciliary vessels is relatively rare. A fourth eye is described in which hypoplasia of the dilator of the iris was found in an excised piece of iris. The pupil had not dilated well before cataract surgery. (6 figures, references.)

GLAUCOMA AND OCULAR TENSION

Bietti, G. B. **Application of carbon dioxide snow in the region of the ciliary body as a means of lowering the intraocular pressure.** Atti del 36 congressa della Soc. oftal. ital. 9, 1947.

In 15 cases of secondary glaucoma carbon dioxide snow was applied to the bulbar conjunctiva in the region of the

ciliary body. Hyperemia is present during the first hour and is followed by a fall in tension that gradually returns to normal in three to six days. I. E. Gaynon.

Bietti, G. B. **Antiglaucomatous operations in trachomatous eyes.** Boll. d'ocul. 27:129-138, March, 1948.

In the Pavia University Eye Clinic, the occurrence of trachoma patients suffering from glaucoma is not rare and even case abstracts illustrate some of the difficulties involved. Five sclerecto-iridectomies, eight trephinations, and one iridectomy were performed. In five eyes the intraocular pressure returned to normal after fistulisation; in six remaining eyes, the pressure was either not lowered or returned to high values after a transient lowering. Anatomic changes may explain this unsatisfactory result: thickening of the conjunctiva, adhesions between conjunctiva and sclera, frequency of hemorrhages, and the postoperative inflammatory reaction in the conjunctival and subconjunctival tissue. These changes make the filtration of the scar more difficult or impossible. Larger conjunctival flaps, larger corneoscleral openings, careful attention to bloodvessels will avoid these failures. Cyclodialysis, diathermocoagulation, and cryotherapy of the ciliary body are the procedures of choice. (1 table, 17 references.)

K. S. Ascher.

Curran, E. J. **Advances in the management of glaucoma.** Postgrad. Med. 3:399-409, June, 1948.

Chronic simple glaucoma is an anatomic defect in the eye which causes it to be functionally unable to meet the requirements of normal production and exit of aqueous. Miotics should be tried. If repeated field studies reveal a diminution, surgery should be resorted to. The various operative procedures are discussed. Iridotomy is believed to be superior to iridectomy. If iridotomy is not sufficient, an Elliot trephining of the sclera with iridotomy is advocated. I. E. Gaynon.

Esterman, Benjamin. **Headache as a symptom of chronic glaucoma.** M. Cl. North America pp. 839-844, May, 1948.

The headache of chronic simple glaucoma is usually supraorbital or frontal, and tends to come on in the evening or in dim illumination. Occasionally it is present on arising and lasts less than one hours. It is most common at the age of marked presbyopia and the symptoms may be induced by such vasomotor stimuli as heat, cold, and strong coffee.

I. E. Gaynon.

Magitot, A. **Provocative tests in glaucoma.** Ann. d'ocul. 181:338-350, June, 1948.

Provocative tests are not of great practical value. At best they give presumptive evidence, especially if positive. Atropin, homatropin or other mydriatics and cycloplegics are not always followed by increased tension in primary glaucoma. Exposure to dark for 30 to 60 minutes frequently increases tension in the glaucomatous for about one hour. Pupillary dilatation and altered pituitary melanophore function are apparently causative. Caffeine administered parenterally or orally was followed by increased ocular tension in 43 percent of a series of normal subjects and by diminished tension in 27 percent. In the glaucomatous the percentages were only slightly different. Although bodily intravenous pressure parallels intraocular pressure, increased intravenous pressure of the head does not aggravate glaucoma. Increased intravenous pressure may be produced by lowering the head, cessation of breathing, stricture of the neck, or by placing an extremity in ice water. The ingestion of large amounts of water preferably on waking, was followed by increased ocular

tension in 82 percent of a series of patients with primary glaucoma.

CRYSTALLINE LENS

Bietti, G. B., Nižetić, B., Jr. **Tissue therapy of Filatov in degenerative chorioretinitis.** Atti del 36 congressa della Soc. oftal. ital. 9, 1947.

Twenty-five patients with various types of degenerative chorioretinitis were treated with placental extract, codliver oil and aloe. Of these 11 had improved objectively, nine subjectively, two became worse and three were unimproved. The annular scotoma was reduced in two patients and the visual field increased in ten. (1 table.) I. E. Gaynon.

Cordes, F. C. **Surgery of congenital cataracts.** Am. J. Ophth. 31:1073-1084, Sept., 1948. (6 figures, 35 references.)

Guyton, J. S. **Prevention and management of complications of cataract extraction.** Am. J. Ophth. 31:1085-1096, Sept., 1948. (1 figure.)

Lancher, A. J. **Cataract surgery in the young diabetic.** Surg. Clin. North America pp. 508-512, April, 1948.

Two patients with bilateral senile cataract, one a women aged 34, the other a man of 46 years were operated on after adequate treatment with insulin. In the first an extracapsular extraction was performed, in the second the intracapsular technique was successfully carried out.

Proper preoperative care and tight section closure by corneoscleral sutures should make the diabetic no greater risk than other patients. Francis M. Crage.

Rossano, R. **Total lens extraction by massage.** Ann. d'ocul. 181:364-372, June, 1948.

Preliminary corneal massage softens the eye and thereby apparently facilitates lens extraction. It is accomplished by means of a Daviel spoon. Most of the force is applied at the lower limbus. The usual cataract surgery then follows.

Chas. A. Bahn.

Theobald, G. D., and Haas, J. S. **Epithelial invasion of the anterior chamber following cataract extraction.** Tr. Am. Acad. Ophth. pp. 470-481, May-June, 1948.

This malignant complication occurs approximately once in every one thousand cataract extractions. In the series of 14 cases discussed, implantation most frequently occurred because of the inclusion of a tongue of conjunctival or corneal epithelium in a technically imperfect wound. In five cases epithelization was actually traced through the wound, and it could probably have been traced by means of serial sections in the others. Delayed healing occurred with severe chronic iritis in eight eyes. Four were diagnosed clinically by a thin white line on the posterior surface of the cornea. This complication can be prevented by a limbus based flap, preferably concentric with the limbus which would adequately cover the wound with an intact layer of conjunctiva. Chas. A. Bahn.

RETINA AND VITREOUS

Belmonte González, Nicolás. **The pathogenesis of hypertensive retinopathy.** Arch. Soc. oftal. hispano-am. 8:478-487, May, 1948.

Ocular fundus, blood-pressure and retinal vascular pressure, urinalysis, blood urea, visual acuity, and the arterio-venous index were studied in 116 hyperten-

sive patients. Without giving the details of the study, the author concludes that stellar retinitis, with edema, exudate, and hemorrhage, represents the specific response of the retina to anoxia. Anoxia may be caused by a constriction of the afferent vessels, an impediment to the venous return, lack of oxygen in the blood, and intoxication of the retinal cells which abolishes their capacity to use the available oxygen. Before the appearance of a hypertensive retinitis the imminence of anoxia is indicated by a relative retinal hypertension. Ray K. Daily.

Biro, I. **The present state of the problem of retinitis pigmentosa.** Brit. J. Ophth. 32:411-415, July, 1948.

Although retinitis pigmentosa is most probably caused by disorders of the pituitary gland and to the surrounding diencephalon, it is not a single disease. Two groups are recognized: the inherited and the autonomous; the former may be dominant and recessive. The great majority of the inherited cases are recessive. The autonomous cases are secondary and follow the exanthemata, typhus, malaria, trauma, inflammations, vaccination, persistant vascular spasms and irregularities of nutrition. The author states that there is a clinical difference between the two types but fails to describe that difference.

The outlook for the inherited type is hopeless while that of the secondary type is more encouraging. The author believes that the work of Filatov should receive attention. In 1945 Filatov wrote of treating 110 cases of retinitis pigmentosa with "tissue therapy" but failed to publish the results of these experiments.

Morris Kaplan.

Budde, H. **Cure of a glioma retinae by radium.** Klin. Monatsbl. f. Augenh. 113: 51-53, 1948.

A one-year-old child had bilateral glioma. The eye with the more advanced tumor was removed and the orbit treated with 280-percent HED X ray filtered through 1 mm. of copper. The other eye was subjected to radium treatment with a total of 300 mgh given in two sittings. The tumor subsequently became smaller and only a big white scar was seen in the fundus six years after treatment. An irradiation cataract developed and had to be removed three years later. Vision is now 5/15. A short survey is given of the gliomas treated by X ray or radium, that have been reported. (References.)

Croll, L. J., and Croll, M. **End results in retinal detachment.** Am. J. Ophth. 31: 1107-1121, Sept., 1948. (1 table, 16 figures.)

Fieandt, von O. **Experiences with transplantation of human vitreous.** Ophthalmologica 15:257-268, May, 1948.

The author has performed five vitreous transplantations on four human eyes with persistent, heavy posttraumatic vitreous opacities. Normal vitreous was obtained from normal human eyes a few hours after death. A strictly sterile surgical technique was observed during the removal of the vitreous from the donor's eye. The remarkable feature in the author's small series is the occurrence of a severe inflammatory reaction in two of his cases which caused atrophy bulbi in one and led to enucleation in the other case. To explain these severe reactions Fieandt following the suggestion of Hobart (*Arch. of Ophth.* 10:237, 1933) tested some patients for sensitivity to their own vitreous proteins. The results were equivocal. To the reviewer it seems that the possibility of a bacterial inflammation should have received more serious consideration. Only one of Fieandt's patients derived some definite visual benefit from the transplantation. There is no indication whatsoever that aspiration of

cloudy vitreous and its replacement with sterile saline solution would not have led to the same result. Peter C. Kronfeld.

Gorduren, S. **Six cases of scintillatio albescens.** Brit. J. Ophth. 32:435-439, July, 1948.

Six cases of snowball opacities of the vitreous are briefly described. The endogenous deposits in the vitreous are very rare and have been reported in 32 of 82,732 patients and in 40 of 65,000 patients. Two types are recognized: asteroid hyalitis which consists of white spherical bodies in normal vitreous, and synchisis scintillans in which sparkling gold particles appear in a fluid vitreous. It is essentially a disease of old age, and almost always unilateral. The bodies are composed of calcium soaps and are said to be associated with general debilitating diseases but this was not the case in this series. Five of these six had incipient or immature cataract in both eyes.

Morris Kaplan.

Jonkers, G. H. **Seasonal variations in the occurrence of retinal detachments.** Ophthalmologica 115:308-315, May, 1948.

A publication by R. Weekers (Ophthalmologica 110:218, 1945) caused the author to investigate whether or not the onset of retinal detachment was in any way seasonally influenced. The records of retinal detachment in 836 patients with definite histories concerning the time of onset served as the basis of this study. All these patients had contracted the detachment on Dutch soil and were treated for it at Weve's clinic in Utrecht. In this material Jonkers found the same seasonal peak in June that Weekers had observed in Belgium. Peter C. Kronfeld.

Jonkers, G. H. **Seasonal variations in the occurrence of retinal detachments.** Ophthalmologica 115:316-318, May, 1948.

In the material of the Eye Clinic of the University of Bern no significant seasonal influence could be recognized in the occurrence of spontaneous retinal detachment. This conclusion was based on the history and findings in 197 patients with retinal detachment. Similar studies in Belgium (Ophthalmologica 110:218, 1945) and in Holland (Ophthalmologica 115:308, 1948) did suggest a seasonal factor. Peter C. Kronfeld.

Lloyd, R. I. **Senile macular lesions.** Am. J. Ophth. 31:1135-1146, Sept., 1948. (15 figures, references.)

Lijó Pavía, J. **Detachment of the vitreous in chorioretinitis, and alterations of the macula.** Rev. oto-neuro-oftal. 23: 25-29, April-June, 1948.

The author describes and discusses a case of chorioretinitis with cicatrix and macular changes, in which he was able to discern a "hole" in the posterior surface of the vitreous at the site of the fundus lesion, and posterior vitreous separation. Drawings and stereophotographs of the fundus clearly describe the lesions. (4 figures, bibliography.) Edward Saskin.

Riddell, W. J. B. **Detachment of the retina.** Medical Press 219:323-325, April 14, 1948.

The short review of the subject is one of the articles in the series of "Modern treatment in General Practice." It concerns itself with the etiology, symptomatology, ophthalmic examination, and operative measures employed in the disease. Much credit belongs to Gonin for his painstaking work. There have been too many good results following surgery to assume a pessimistic attitude in the prognosis of retinal detachment.

Francis M. Crage.

Rosengren, Bengt. **The value of anticoagulant drugs in thrombosis of the retina.** Acta Med. Scandinav. pp. 212-217, Suppl. 206, 1948.

In the treatment of six cases of tributary venous thrombosis with dicumerol, thrombolysis occurred in three about four weeks after the therapy was started. The percentage of successes in these cases undoubtedly is reduced where vascular sclerosis and compression from without exist. The age range in the author's cases was 57 to 76 years. Francis M. Crage.

Silván López, Fernando. **Grouped pigmentation of the retina.** Arch. Soc. oftal. hispano-am. 8:448-456, May, 1948.

Two cases are reported. One patient had a negative family history and no other anomalies except the retinal pigmentation, the other had a number of associated congenital anomalies, traced through three generations. A 15-year-old boy had twelve groups of slate-colored foci in the inferior nasal sector of the left fundus. They were darker near the disc, and less pigmented further away. The number of foci in a group varied from a solitary patch close to the disc to 15 or 20 small ones in the periphery; the majority of the groups contained two or three. Each group gave the impression of having been formed by the fragmentation of a single focus. The contours of the pigment spots were well defined, and some had a fine granulation at the edges. The pigmented areas obscured the choroidal network, and the retinal vessels passed over them without any alteration in their level. Visual acuity and fields were normal. The other patient, 10 years old, with strabismus and amblyopia of the left eye, had three groups of slate colored foci in the fundus of this eye. They were in the horizontal meridian on the nasal side, eight disc diameters from the disc. This patient was of a hyperexcitable temperament, and in addition to the retinal pigmentation, had syndactyly of the toes and a misshaped auricle. His maternal grandmother was blind from glaucoma; the paternal grandfather was a drunkard. The father and two brothers had the same anomaly of the ears, and one brother had syndactyly of the toes. The pathogenesis of this anomaly is discussed. (2 figures). Ray K. Daily.

Soloff, L. A., and Bello, C. T. **The relationship of retinal hemorrhages in hypertensive patients to cerebral hemorrhage: a comparison of the retinal picture in hypertensive individuals who died of heart failure with those who suffered a cerebral hemorrhage.** Am. J. M. Sc. 215:660-664, June, 1948.

A review was made of the records of all patients with hypertension who had been admitted to Temple University Hospital between 1941 and 1946 and had died or had cerebral hemorrhage. It was found that retinal hemorrhages occurred in 77 percent of 18 patients who died of cardiac failure without cerebral hemorrhage, in 29 percent of 17 patients who had a cerebral hemorrhage, and in patients who had large regions of spasm with or without a marked sclerosis. Retinal hemorrhages cannot be used as a prognostic sign of future cerebral hemorrhage, as they occur more frequently in those who ultimately die of cardiac or renal failure without a massive cerebral hemorrhage. (6 tables, references.)

Bennett W. Muir.

Vetter, J. **Retinal detachment in a case of retinitis pigmentosa.** Klin. Monatsbl. f. Augenh. 113:53-59, 1948.

The combination of pigment degeneration of the retina with detachment is very rare. The case of a young man is described who developed a detachment in one eye and was successfully treated by repeated electrocoagulation. The pigmentary degeneration advanced after this operation and, after nine years, had led to tubular fields in both eyes. The author points out that in spite of the supposed coalescence of retina and pigment epithelium in pig-

mentary degeneration the union does not seem strong enough to prevent hole formation and detachment in predisposed retinas. This is particularly true in the very early stages, when sprouts from the pigment epithelium have not yet invaded the retina. The relatively good result in the author's patient seems to recommend detachment surgery, even if the detachment is complicated by an existing retinal pigment degeneration. (References.)

Max Hirschfelder.

Weekers, R., and Roussel, R. **The critical flicker frequency after successful operations for retinal detachment.** Ophthalmologica *115:297-308, May, 1948.*

In previous papers Weekers and Roussel applied the method of determining the critical flicker frequency to the study of various retinal and optic nerve diseases. It proved to be a very sensitive index of visual function. Application of this method in cases of cured retinal detachment reveals permanent impairment of visual function even when the retina had been detached for only one month. The operation for detachment of the retina is an urgent one. Every postponement lessens the prospects of healing and also the postoperative restoration of visual function.

OPTIC NERVE AND CHIASM

Bruetsch, W. L. **Etiology of optochiasmatic arachnoiditis.** Arch. Neurol. and Psychiat. *59:215-228, Feb., 1948.*

Syphilis is the most common, and otitis media is another well recognized cause. The role of trauma is difficult to understand. Arachnoidal adhesions alone may be responsible for atrophy of the superficial nerve fibers, but anatomical experience tends to show that they do not produce atrophy of the nerves on a large scale. The tendency to report unexplained cases of optic nerve atrophy under the heading of optochiasmatic arachnoiditis is increasing, and in many of these there probably is a primary morbid process within the chiasm and nerves. The full status of this condition is still not at hand. (4 figures, references.)

Bennett W. Muir.

Stansbury, J. R. **Optic atrophy in diabetes mellitus. A report of three cases in one family.** Am. J. Ophth. *31:1153-1163, Sept., 1948. (6 figures.)*

Tetzu, I., Blatt, N., and Silvian, J. **Interstitial optic neuritis consecutive to a furuncle in the nasal vestibule.** Arch. d'opht. *8:264-269, 1948.*

The authors report the case of a man of 55 years with a furuncle in the left nares of four or five days duration, and with swelling of the lower lid. He had been receiving sulfonamide and penicillin therapy. The vision of the right eye was normal but that of the left was reduced to light perception. Fundus examination showed an atrophy of the optic nerve. After two days of observation and local treatment, the furuncle came to a head and was evacuated. The patient was treated with dionin, strychnine, vitamins B and C, cyclotropine, intravenous glucose, cascosan, transpupillary infrared radiation, and ultraviolet light; there was slight improvement in vision over a period of three weeks. After ruling out syphilis and sinusitis as possible factors, the authors conclude that the optic atrophy was caused by the furuncle but fail to explain the rapid development of the atrophy. They review the literature on the subject of pyogenic infections of the face and their orbital and intracranial extensions.

NEURO-OPHTHALMOLOGY

Chamlin, Max. **Visual field studies in neurosurgery.** Surg. Cl. North America pp. 432-437, April, 1948.

Field charts showing enlargement of blind spots and homonymous field defects were proved to have provided considerable help in diagnosis of brain tumors. In some cases this evidence was corroborative, in others a stimulant to further studies, and in still others it was the most important finding in diagnosing the existence and location of a lesion. They are of great value in differentiating inflammatory lesions such as optic neuritis and retrobulbar neuritis from non-inflammatory diseases. Francis M. Crage.

Ethelberg, S., and Jensen, V. A. **"Choked disc" in neurosyphilis.** Acta. Psychiat. and Neurol. 23:49, 1948.

The author finds lumbar and cisternal puncture contraindicated when papilledema is present, especially since a positive Wassermann reaction in the spinal fluid does not give conclusive evidence of the syphilitic origin of a given intracranial neoplasm.

If ventriculography reveals a normal or slightly increased pressure without signs of tumor, we may ascribe the papilledema to cerebral meningitis and call it meningeal papilledema. If there is no sign of tumor, but the intracranial pressure is increased, then it may be very difficult to distinguish ophthalmoscopically between meningeal papilledema and papilledema produced directly by the intracranial pressure. In meningeal papilledema the veins are slightly engorged and exudates or hemorrhages are few or absent whereas we find a typical choked disc with pronounced engorgement of the veins and typical extravasates in syphilitic basal meningitis or where the pressure is due to a large solitary gummatous tumor. Apart from antisyphilitic therapy and fever treatment decompression may be necessary to prevent the papilledema from developing into secondary atrophy. Since the operation is not entirely an indifferent procedure we may watch and wait till the edema develops into a regular choked disc.

If ventriculography indicates tumor, craniotomy should be done in all cases. Most of the tumors are of nonsyphilitic origin, but even if the lesion is gummatous, which is very rare, craniotomy is indicated because the intracranial gumma is resistent to chemotherapy.

R. Grunfeld.

Godtfredsen, Erik. **Pathogenesis of cranial nerve lesions, notably ophthalmoplegias, complicating herpes zoster ophthalmicus.** Acta Psychiat. and Neurol. 23:69, 1948.

The author reports eight cases of herpes zoster ophthalmicus associated with cranial nerve lesions. The cutaneous extension, severity, duration, and prognosis do not differ from what is seen in other cases without attending neurologic symptoms. The lesion is a radiculomeningitis that proceeds from the Gasserian ganglion in which the herpes virus is localized. In the ganglion cells we find a very pronounced hemorrhagic inflammatory reaction with necrobiosis, necrosis, and consecutive regional meningitis. The inflammation spreads along the first branch of the trigeminal nerve centripetally and centrifugally. Eventually the inflammation reaches the cavernous sinus where it involves the third, fourth and sixth nerves. The involvement of the seventh nerve must be considered a manifestation of brainstem encephalitis. The zoster virus spreads centripetally into the brain stem along the descending root of the trigeminal nerve. The facial nerve fibers and the descending root of the trigeminal nerve are intimately related in the pons. R. Grunfeld.

Klein, R., and Attlee, J. H. **The syndrome of alexia and amnesic aphasia. Subarachnoid haemorrhage with symptom of partial occlusion of the spinal subarachnoid space.** J. Ment. Sc. 94:59-69, Jan., 1948.

The article describes a complete study of a case of subarachnoid hemorrhage in a women, aged 47 years. Neurologically the disease was followed through coma, mania, confusion, and finally convalescence. The neurologic signs were varied and memory suffered the most. Retinal and vitreous hemorrhages and an upper right-sided homonymous quadrantic hemianopia were the outstanding ocular defects. The latter remained unchanged but practically all the other symptoms disappeared at the end of three months. The field defect was ascribed to a break in the lower radiation fibres. Right-sided hemianopic defects when associated with alexia arise from a left lingual gyrus lesion in a right handed person.

Francis M. Crage.

May, P. R. A. **Pupillary abnormalities in schizophrenia and during muscular effort.** J. Ment. Sc. 94:89-98, Jan., 1948.

Dilatation of the pupil with impaired light sensitivity has been known to occur after muscular effort and in catatonic schizophrenia where the sign was termed "catatonic pupil." In such cases dilated pupils and impaired light reflex were usually bilateral. The author's investigations were made on 343 male schizophrenics and 100 mentally normal males all under the age of 55. Studies were made of the pupils in respect to their equality and the reactions to pain, light and muscular effort. Diminished pupillary response occurred very frequently with the above mentioned reactions in all of the schizophrenics. These abnormal changes might be correlated with the schizophrenic's lack of normal emotional response to the outside world. The pupillary signs found in these cases would complicate the differential diagnosis between schizophrenia and neurosyphilis.

Francis M. Crage.

Simpson, J. F. **Horner's syndrome due to an osteochondroma of the first rib.** Canad. M.A.J. 59:152-155, August, 1948.

A case of Horner's syndrome in a woman caused by an osteochondroma of the left first rib is reported. The author believes it to be the first reported case of that nature. Symptoms were apparent at the age of 7 years, the syndrome was first noticed at the age of 14, the tumor was identified at the age of 17, and removed at 34 years of age. A review of anatomy, physiology, and etiology is given. (8 figures, references.) Bennett W. Muir.

Stengel, E. **The syndrome of visual alexia with color agnosia.** J. Ment. Sc. 94:46-58, Jan., 1948.

Word blindness as a loss of visual memory has been ascribed to a localized cerebral lesion and also to a general impairment of brain function. The two cases presented occurred in men, aged 63, and 68 years of age. Each had a right-sided hemianopia, word blindness, and abnormal color vision. The lesions in both cases were obviously vascular. A discussion of the location of lesions causing this complex follows. Francis M. Crage.

14

EYEBALL, ORBIT, SINUSES

Barnett, H. N., and Ford, R. **Ophthalmic and other affections predisposed to by deformities and caused by sepsis of the nose.** Medical Press 219:239-245, March 17, 1948.

Deformities in the nasal septum and turbinates are considered the main cause for septic infections in the sinuses. The sinusitis results from the mechanical interference with the discharges from the sinuses. The treatment when surgical

must correct both the sinus lesion and the obstructive defect.

Such ocular conditions as dilated pupil, ptosis, corneal ulcers, keratitis, iritis, choroiditis, retrobulbar neuritis, and optic neuritis have been caused by sinus infections. Illustrative cases are presented. The rhinologist is advised to puncture and irrigate sinuses in disturbances of undetermined etiology, despite negative nasal and X-ray findings. This is especially true in retrobulbar neuritis. Contrary to the conclusion of others, the authors feel that the latter disease can be frequently caused by sinus disease, and, because no definite inflammation is present in the nerve, they feel that the symptoms are the result of pressure on the optic nerve by the orbital edema adjacent to the affected sinuses. They feel that a better term for the disease is "pressure paresis of the optic nerve." A strong appeal is made for a thorough nasal study in eye diseases of unknown etiology. Francis M. Crage.

Fischer, J. T. **Basedow's hyperophthalmia.** Rev. oto-neuro-oftal. 23:29-35, April-June, 1948.

This paper is a continuation of investigations described in the previous issue. To diagnose this condition, several criteria must be kept in mind. The patient complains fundamentally of his eye and vision, the thyrotoxicosis responds to medication, there is a hypometabolism with or without hypothyroidism, and an increase in thyrotropic hormone. Thyroidectomy is contraindicated. The exophthalmos is a true edematous phenomenon, and is attended by the vices of any proptosis. The condition is abetted by the administration of estrogenic hormones and iodothyroxin; relief may also be obtained by radiotherapy directed to the hypophysis and the orbit. In cases of severe proptosis, decompression of the orbit may be attempted.

Edward Saskin.

Loddoni, G., and Duc, C. **Ageing of the human eye.** Boll. d'ocul. 27:139-192, March, 1948.

This comprehensive review, consisting of 50 pages of condensed factual reports and two pages of references, can not be abstracted briefly. The anatomic and functional changes of the eye during senescence are described. Scleral hyalinization (Roper) is not mentioned. Intravascular pressure, pupillary changes, visual field defects and ageing of the color sense and of light perception are discussed. K. W. Ascher.

Lloyd, R. S., and Jones, R. M., Jr. **The Cutler-Guyton eye implant and prothesis: two cases.** Military Surg. 101:205-207, March, 1948.

Two cases in which the Guyton modification of the Cutler implant has been used are described. The implants are well tolerated, there has been minimal exudate and there has been 90 percent motility. The operative technique is described.

I. E. Gaynon.

Morone, G. **Cutaneous fibromatosis with orbital angiofibroma.** Boll. d'ocul. 27:193-199, March, 1948.

Numerous fibropapillomas of varying size were located on the back and on the chest of a 45-year-old patient who had noticed a slight protrusion of his left eye three years before the operation. Transpalpebral orbitotomy revealed the presence of a fibroangioma. The author did not find an identical case report in the literature but the coincidence of Recklingshausen's disease and various tumors has been reported previously. (4 photographs, bibliography.) K. W. Ascher.

15

EYELIDS, LACRIMAL APPARATUS

Callahan, A. **Reconstruction of the canthi.** Tr. Am. Acad. Ophth. pp. 486-496, May-June, 1948.

The outer canthus is normally higher when the lids are closed, but lower when they are opened. The reëstablishment of posterior pull is of special cosmetic importance. This is normally accomplished medially by Horner's muscle and laterally by the canthal ligament.

Two holes are made in the anterior or posterior crest with a dental drill, avoiding perforation of the nasal mucosa. A stainless steel wire is directed through the upper opening, passes between the bone and nasal mucosa and emerges through the lower opening. The ends are then passed through the canthal ligament or tarsal plates and are twisted rather than knotted. This basic technique is necessarily modified to meet individual problems. A series of 37 patients operated on by this method is analyzed. Numerous specific case reports and 27 illustrative figures are presented.

Chas. A. Bahn.

Callahan, Alston. **Severe lid deformities.** Plast. and Reconst. Surg. 3:456-463, July, 1948.

The management of bilateral multiple lid deformities is illustrated with a detailed case report. Loss of skin is replaced with a free skin graft, and displaced tissues are rearranged with a pedicle flap. Intermarginal lid adhesions are utilized to prevent contraction. When extensive repair of the lid is required after the eye has been removed, the graft or flap is kept under more adequate tension if an acrylic conformer is kept constantly in the socket. This ophthalmopedic aid also maintains ample space for an artificial eye when surgery is concluded. Intermarginal lid adhesions are divided after three months. A severed palpebral ligament of the upper lid of the other eye is reattached to the bone with wire. (7 photographs, 4 drawings.) Alston Callahan.

García Miranda, Ramón. **Sjögren's syndrome associated with acne rosacea.** Arch. Soc. oftal. hispano-am. 8:590-602, June, 1948.

A case of Sjögren's syndrome and acne rosacea is reported and the newer literature is reviewed with special reference to hormone therapy. A woman, 58 years old, developed in the course of nine years, Reynaud's disease, keratoconjunctivitis sicca, acne rosacea of the cornea, and a general dryness of the mucous membranes, anosmia, loss of taste, and menstrual irregularity. Her ocular as well as general symptoms improved rapidly on treatment with polyvitamins, liver extract, and perandren. Because of the high cost of perandren, its use was discontinued, and the symptoms recurred in their original intensity. She was then given cortical hormone instead of perandren and she again improved remarkably. The local treatment consisted of sodium bicarbonate eye baths. (2 figures.)

Ray K. Daily.

Kettesy, A. **On genesis and operation of the cicatricial (trachomatous) entropion of the upper lid.** Brit. J. Ophth., 32: 419-423, July, 1948.

Most operations for entropion of trachoma fail because it is erroneously assumed that the cause of the entropion is the progressively incurved tarsus. Actually this incurving of the tarsus occurs quite late in the process and the real cause is the obliteration of the intermarginal space by the contraction of the scars along the subtarsal sulcus. The author has devised his own operation which aims at the remodelling of the intermarginal surface. The upper lid is everted by Liebermann's sutures and the tarsus is incised through and along the line of scars in the sulcus. Three mattress sutures are placed in the conjunctival side of the section and an incision is made just behind the marginal tarsal strip through to the skin. The mattress sutures are then brought through the

tarsal strip and loosely knotted; then the loose ends are brought out through the skin above and tied. Vaseline pressure dressing is applied and the knots are removed after two days. The author dislikes the use of beads, rolls or pads beneath the skin sutures. (5 illustrations.) Morris Kaplan.

Risdon, Fulton. **The eyelid and socket surgery.** Plast. and Reconst. Surg. 3:454-455, July, 1948.

Skin grafts of .018 are used to reconstruct either upper or lower eyelids. If all four lids require skin grafting, the upper lids are done at one operation, the lower lids at a second. Intermarginal adhesions have not been satisfactory in the author's hands.

A thin lead plate with an intermediate piece of lint is laid over the graft and sutures tied around it to maintain pressure.

In the reconstruction of a contracted socket, the mucous membrane remaining is not removed and a skin graft of .018 thickness is used to cover the raw surfaces produced by the extension. Dental compound mould is preferred. Glass artificial eyes are preferred. Fascia lata strips are used to suspend ptosed lids to the occipitofrontalis muscle.

Alston Callahan.

Rosas Costa, M. T. **Treatment of styes by intrapalpebral penicillin injection.** An. argent. de oftal. 8:13-16, Jan.-Feb.-March, 1947.

In order to achieve a quick and efficient therapeutic result in the treatment of hordeola and to prevent any complications, the author advises the usual hot wet compress followed by an injection of 50,000 units of penicillin in about one and a half cc. of 2-percent novocaine. The healing is rapid, there is very little local reaction, no other medication is necessary, and one injection usually suffices. (Bibliography). Edward Saskin.

Zarrabi, M. **The operation of entropion,** Arch. d'opht. 8:269-270, 1948.

Zarrabi discusses the causes of failures in the surgical treatment of trichiasis and entropion due to trachoma. He describes an operation for which he claims a high percentage of successful results. In his operation two parallel incisions are made in the skin of the lid, the first 2 mm. above the ciliary border and the second 3 mm. above the first. This portion of the skin and of the subjacent tissues down to the tarsus is then excised with scissors. Two parallel incisions are then made in the tarsus 1½ mm. apart, the first incision being made 1 mm. from the lower border, sparing the roots of the cilia. This portion of the tarsus is then excised, the palpebral conjunctiva being left intact. A zigzag suture is then passed through the tarsus and the subcutaneous tissue in such a fashion that when tightened it draws the edges of the tarsal incision together and everts the lid border. The skin itself is not included in the suture. The author states that the operation has been employed on a large scale in Teheran with full satisfaction to patient and surgeon. Phillips Thygeson.

17

INJURIES

Cross, A. G. **The effects of mustard gas on the eyes.** Medical Press 219:281-282, March 31, 1948.

A short historical summary on the use of this war gas is given.

Acute mustard gas keratoconjunctivitis is characterized by the appearance of photophobia and blepharospasm three to eight hours after exposure to the gas. Moderate to severe pain is present in direct proportion to the extent of destruction of corneal epithelium. About 75 percent of the cases were mild and cleared up in about four weeks. Of the remainder,

15 percent with some roughness of the cornea took a little longer and the other 10 percent required many months to heal extensive necrosis of superficial corneal epithelium.

Delayed mustard gas keratitis appeared in a few cases about ten years after exposure to the gas and freedom from ocular symptoms. All these patients gave a history of original treatment of the eyes for as long as six months. The main symptoms were lacrimation, photophobia, and failing vision. The corneal stroma showed dilated vessels and aggregations of caseous material. Ulceration was also present. The vision progressively diminished despite the treatment. The treatment is that of keratitis in general. Contact lenses, where tolerated, were of considerable help to those with irregular corneal astigmatism. The essential cause for the delayed and recurrent corneal ulceration was the presence of masses of cholesterin and fat resulting from the original vascularization in the cornea and limbal region. Once the degenerative process has begun it continues.

Francis M. Crage.

18

SYSTEMIC DISEASE AND PARASITES

Bergstrand, Hilding. **Hypertensive vascular changes in the eye.** Acta Path. et Microbiol. Scandinav. 25:98-106, 1948.

Volhard's theory of spasticity of the retinal vessels rather than a reaction from toxic substance as a cause for the condition known as albuminuric retinitis is rather strongly upheld. The author substantiates this by the ease with which this theory can explain such conditions as eclampsia, chronic glomerulonephritis, and essential hypertension with or without renal disorders.

The histological changes in the vessels of the choroid and retina in essential hypertension and retinal changes are described.

Francis M. Crage.

Chandramowli, A. **Ophthalmology in relation to general medicine.** The Antiseptic 45:433-448, July, 1948.

In this lecture the author deals briefly with a large number of topics. He points out the similarity in the behavior of the eye and other organs to stimulation by drugs, he discusses the medical aspect of eyestrain, and describes ophthalmic manifestations of disease of the blood and cardiovascular system, the organs of respiration, and of diabetes, allergic states, and endocrine disturbances.

F. H. Haessler.

Del Río Cabañas, J. L. **Ophthalmoplegic migraine, caused by a metastatic tumor.** Arch. Soc. oftal. hispano-am. 8: 622-630, June, 1948.

The literature is reviewed, and a case reported. A 66-year-old man with an intestinal neoplasm and bronchial metastasis developed a typical ophthalmoplegic migraine on the right side after a blow in the right temporal region. The third, fourth, fifth and sixth nerves were involved. The ophthalmoplegia is attributed to metastasis at the base of the brain. (6 figures.)

Ray K. Daily.

Ferrié, J. **Complications of relapsing fever.** Ophthalmologica 115:227-240, April, 1948.

A severe epidemic of relapsing fever broke out in Morocco in January, 1945 and spread from there all over North and Northwest Africa. Visual complications were observed chiefly after the use of pentavalent arsenicals. A neurotropism of the spirochete may also have been a factor in causing optic nerve lesions. The lesions were chiefly retrobulbar and often associated with signs of polyneuritis. The author warns against the use of pentavalent arsenicals in the treatment of relapsing fever.

Peter C. Kronfeld.

Holland, H. **Hydatid of the orbit.** Brit. J. Ophth. 32:395-396, July, 1948.

Very briefly the author discusses eight cases of echinococcus cyst of the orbit which occurred in India. In all of them the cyst was in the upper fornix. Proptosis was the most prominent symptom and pain one of the least. Vision was little disturbed unless ulceration of the cornea had developed. It was always unilateral and the diagnosis was made by finding typical hooklets in the fluid obtained by aspiration of the tumor. It is important to completely excise the cyst which is most difficult to do. The author succeeded in two of his patients. Ecchymosis reaction is very severe in patients in whom portions of the cyst remain; however, the prognosis for vision is very good.

Morris Kaplan.

Palmer, R. S., Nyssens, A. F., and White, J. C. **Severe hypertension with papilledema simulating brain tumor.** New England J. Med. 239:322-327, August, 1948.

The similarity in symptoms, physical signs, and spinal fluid findings in patients with severe hypertension with papilledema and in those with expanding intracranial lesions is pointed out. A comparison is made of observations in 30 patients with severe hypertension and papilledema, in 25 patients with expanding intracranial lesions, and in 15 patients with severe hypertension without papilledema. The differential diagnosis between severe hypertension with papilledema and an expanding intracranial lesion with coincident hypertension is discussed and illustrated by a report of three cases. The most important differential characteristic is the slow, steady progression of neurologic localizing signs in brain tumor. Proper evaluation depends upon expert neurologic examination and sometimes upon supplementary pneumograms. In the hands of the writers extensive sympathectomy has been the measure that relieved symptoms, reduced the papilledema and stayed the usual rapid progress of malignant hypertension. It is suggested that denervation of the splanchnic bed abolishes or minimizes the orthostatic pressor responses and thus protects the cerebral circulation. (3 tables, references.)

Bennett W. Muir.

Rosen, E. **Some new concepts concerning ocular complications following vaccination.** Ophthalmologica 115:321-332, June, 1948.

Following the mass vaccination against smallpox in New York City during the Spring of 1947 the essayist observed several cases of ocular complication which he reported in various periodicals. They included such syndromes as interstitial keratitis associated with vestibuloauditory symptoms, metaherpetic keratitis, dendritic keratitis, exudative chorioretinitis, central serous retinopathy, iritis and panophthalmitis, thrombophlebitis and lesions of extraocular muscles. In all these cases the eye complication occurred from 9 to 13 days after the vaccination, which period has become recognized as the incubation period of postvaccinial encephalitis. None of the essayist's cases showed definite signs of encephalitis, but in his opinion "it is not difficult to assume that the eye may be the mirror in which allergic cerebral changes encountered in the postexanthematous encephalitic state may actually be visualized." Since postvaccinial encephalitis is a comparatively new disease first described 23 years ago, it is not difficult to understand the infrequency of observation and recognition of the postvaccinial ocular complications. The clinical manifestations of postvaccinial encephalitis are just as variable as the postvaccinial eye complications. The ophthalmologist is in

an advantageous position to observe post-vaccinial complications.

Peter C. Kronfeld.

Saebo, J. **Xeroderma pigmentosum with affection of the eye.** Brit. J. Ophth. 32:398-411, July, 1948.

Xeroderma pigmentosum is a congenital skin disease which is relatively rare and very difficult of diagnosis. It develops under the influence of sunlight in the course of the first few years of life. Three stages are recognizable: the first is a hyperemic and inflammatory phase most often called ordinary freckles; a second stage is characterized by brown warts and excrescences; and in a third stage malignant growths appear. The disease takes many years to develop but most patients die at an early age. Serious ocular manifestations occur often, such as malignant palpebral affections, pigmented conjunctival tumors, teleangiectases and papillomas. They may spread to all parts of the eye and to other parts of the body.

The author describes three cases which were closely watched for many years. The first two were in siblings in whom the disease was discovered early. Each outcropping was promptly treated with heavy doses of X-ray or radium radiation, with good and apparently lasting results. The third case was not diagnosed for many years. Both eyes had to be removed and the patient died with extensive metastases at the age of 21 years. It is important that even benign-looking tumors in the eyes associated with pigmented spots on the skin be studied most carefully. (10 figures.) Morris Kaplan.

Teichman, B., and Greer, K. C. **Ocular manifestations of myasthenia gravis.** Canad. M. A. J. 59:55-58, July, 1948.

The onset is usually gradual and increased muscular fatiguability is most often observed in the ocular muscles. Ptosis of one or both upper lids is the first symptom in over 50 percent of cases, and soon is associated with variable diplopia. Less frequently the bulbar muscles are involved. A characteristic is the increase in signs and symptoms with bodily fatigue, and regression after rest. Orbicularis weakness is sometimes seen. Pupillary reflexes are not interfered with, and accommodation paresis is rare. Visual acuity and visual fields are not involved. Sometimes symptoms remain evident only in the ocular structures for years although usually they spread to other skeletal muscles. Subcutaneous injection of 1.5 mgm. of progstigmine gave improvement of the levator muscle action in all of one series of cases. The muscles attached to the globe, however, may require a larger dose to improve ocular motility. Two doses of 0.6 gm. each of quinine may be used if the progstigmine gives no results. Myasthenia should be included in the differential diagnosis of external ophthalmoplegia. The exact relationship of the thymus to this disease is not known. However, a patient may benefit from thymectomy. (1 figure, references.) Bennett W. Muir.

19

CONGENITAL DEFORMITIES, HEREDITY

Busacca, A., and Pinticart, de W. E. **Gonioscopic study of a case of posterior corneal embryotoxon.** Ophthalmologica 115:283-290, May, 1948.

In 1920 Axenfeld gave the name posterior corneal embryotoxon to a congenital anomaly of the cornea characterized by a white annular band situated in the deepest layers of the cornea just inside the limbus. In the paper under review the clinical and gonioscopic findings in such a case are described in detail and well illustrated. The white band proved to be

an anterior extension of the corneoscleral trabeculum. The glistening white line that formed the inner border of the band was the thickened tip of the scleral septum which is the posterior extension of sclera into the cornea and serves as foundation for the corneoscleral trabeculum and the canal of Schlemm.

Peter C. Konfeld.

Crespi Jaume, G. **Congenital ocular melanosis.** Arch. Soc. oftal. hispano-am. 8:437-447, May, 1948.

This is a comprehensive review of the literature, and a report of three cases. A child, four years old, had a darkly pigmented zone 4 to 5 mm. wide surrounding the left cornea, except for a small area on the nasal side. Its outer edge was festooned, and the inner edge was on the limbus. The iris was very dark, and the fundus so deeply pigmented as to obscure the perivascular choroidal spaces. A woman, 58 years old, had twelve dark patches in the superior and temporal portion of the right eyeball. They were separated from one another by areas of normal sclera. The iris was densely pigmented, except for one sector below, where its color and structure were similar to that of the left eye. The third patient, 15 years old, had a choroidal nevus, and small pigment spots on the disc. (3 figures.) Ray K. Daily.

Papolczy, F. **Congenital cyclopia and orbital cyst together with other developmental anomalies on the same side of the face.** Brit. J. Ophth. 32:439-443, July, 1948.

The author describes a baby with characteristics of congenital cyclops confined to the right side. A proboscis-like tube, 3.5 cm. long and 1.5 cm. in diameter, extended from the right inner canthus down along the nose and had a navel-like depression on its distal end. The lower lid was violet and was greatly enlarged into a very soft cyst. There was a hare-lip and cleft palate on the right side and no eyeball. The left side was normal. The proboscis and the cyst were removed. It was found that the tube had all the tissues of the normal nose and the cyst had only layers of epithelium. Eight days after this operation the baby developed pneumonia and died. At necropsy it was seen that the soft parts of the orbit contained tissues of lens, retina, choroid, ciliary body, iris and pigment epithelium.

Morris Kaplan.

HYGIENE, SOCIOLOGY, EDUCATION, AND HISTORY

Birren, F. **The ophthalmic aspects of illumination, brightness and color.** Tr. Am. Acad. Ophth. pp. 566-584, May-June, 1948.

In industry, glare and other symptoms result from maladjustment between increased illumination and environmental brightness. Illumination which may appear excessive is frequently made to seem normal by adjustment of surrounding brightness. Flooring materials, desks, filing cabinets, woodwork and paints enter into the adjustment. Fairly critical seeing usually requires 25 to 35 foot candles and general illumination should ordinarily not exceed 50 foot candles. The theory of uniform brightness is both impractical and misleading. The illumination of the work should moderately exceed its surroundings. Monotony, however, should be avoided. The psychologic aspects of vision including color constancy are of special importance. Ocular fatigue is largely muscular rather than retinal. The constant effort to improve vision by ineffectual adjustments causes the symptom complex known as eye strain. Chas. A. Bahn.

Currie, J. G. D. **An English experience.**

Tr. Am. Acad. Ophth. pp. 584-588, May-June, 1948.

In an English factory which produced precision work an excessive number of employees required ophthalmic treatment. A large number of the employees were not visually suited for accurate near work, ametropias were not adequately corrected, and lighting facilities were inadequate. A marked decline in the number of employees requiring ophthalmic treatment was noted when these conditions were corrected. Chas A. Bahn.

Erpf, S. F., Dietz, V. H., and Wirtz, M. S. **Ophthalmoprothesis, U. S. Army World War II.** Military Surg. 101:405-408, Nov., 1947.

A short history of the development of the artificial eye program is presented. I. E. Gaynon.

Franklin, C. F., Sr. **A bacteriological comparison of penicillin and silver nitrate for prophylaxis against ophthalmia neonatorum.** Military Surg. 102:179-184, March, 1948.

Two and one-tenth percent of the infants exhibited pus while in the nursery after penicillin prophylaxis and the cultures were positive in 80 percent of these. Six percent of the infants exhibited pus after silver nitrate prophylaxis. Fifty-two percent of the cultures were positive in both groups of infants who exhibited ocular abnormalities other than pus. After penicillin prophylaxis 3.1 percent of the eyes exhibited pus at home and 3.3 percent of the cultures of these eyes were positive. After silver nitrate prophylaxis, 2.4 percent exhibited pus in the eyes at home and 100 percent of the cultures were positive. The gonococcus was found in one case after silver nitrate prophylaxis. I. E. Gaynon.

Koch, F. L. P. **Some practical aspects of geriatric ophthalmology.** Geriatrics 3: 163-165, May-June, 1948.

Early or impending pathologic changes in the elderly may be determined by examinations. Corrective measures may be instituted at the optimum time. I. E. Gaynon.

Kefalas, A. **Eye hazards and safety practices in the Wearside shipyards.** Brit. J. Indust. Hyg. 5:51-69, April, 1948.

Of a group of 100,000 miscellaneous accidents 14,722 occurred in the eye. Eye injuries consist of flash injuries, burns or scalds, mechanical trauma, foreign bodies and hot foreign bodies. (10 tables, 7 figures.) I. E. Gaynon.

Morgan, W. G., and Stump, N. F. **Important uses of industrial vision tests and the medical director.** Indust. Med. 17:253-258, July, 1948.

Employees whose visual skills passed the minimum requirements for the job had greater comfort, simplification of work tasks, increased earning, decreased rejected materials at inspection, greater safety at the job, reduced minimum pay make-up and decreased absenteeism. I. E. Gaynon.

Saunders, E. E. **Navy eye-correction, eye-protection program.** Tr. Am. Acad. Ophth. pp. 562-565, May-June, 1948.

The numerous physical and mental factors that affect the visual efficiency of the individual are discussed briefly. The program instituted by the Navy includes the examination of civilian employees with the Ortho Rater or/and Sight Screener to test simultaneous binocular vision, visual acuity, stereopsis, muscle balance and color discrimination. To facilitate minimal transportation expense, workers are examined preferably in larger key stations and smaller supplementary stations, if necessary. The neces-

sity of occupational glasses in specific cases is stressed and illustrated.

Chas. A. Bahn.

Stewart, R. E. **Plastic artificial eye and restoration program, Veteran's Administration.** Military Surg. 101:396-404, Nov., 1947.

A step by step account of the procedure used in the manufacture of ocular plastic prosthesis is given.

I. E. Gaynon.

Vail, D. **Opportunities and responsibilities of ophthalmology.** Tr. Am. Acad. Ophth. pp. 359-366, March-April, 1948.

In industrial practice ophthalmologists have not fulfilled their duties. In the stress of private practice, most ophthalmologists have not taken the time and effort which is necessary for the reasonable understanding of industrial needs. Problems such as job analysis, illumination in industry, and more efficient industrial methods in the prevention and treatment of employees are important in industrial ophthalmic practice, but unsolved. Generally speaking, ophthalmologists feel that mass refraction means inefficient refraction. The relationship between ophthalmologists and technicians such as optometrists is discussed at some length. Chas. A. Bahn.

Young, M. N. **Ophthalmic practice with an Army Hospital in North Africa and Southern France Ports.** Military Surg. 101:211-212, Sept., 1947.

Ophthalmic practice consisted for the most part of clinic practice comprising refractions, spectacle fittings, physical examinations and consultations. Diseases encountered were keratoconjunctivitis, corneal ulcer and malarial herpetic keratitis. Surgery was performed for orbital fractures, foreign bodies, hordeolum, chalazion, lacerations, pterigium and intraocular foreign bodies. I. E. Gaynon.

NEWS ITEMS

Edited by DONALD J. LYLE, M.D.
601 Union Trust Building, Cincinnati 2
News items should reach the editor by the 12th of the month

DEATHS

Dr. Robert James Lynch, Des Moines, Iowa, died May 28, 1948, aged 67 years.

Dr. Percy Jay Ross, Chicago, Illinois, died September 28, 1948, aged 46 years.

Dr. Vivean Visscher Wood, St. Louis, Missouri, died June 20, 1948, aged 61 years.

MISCELLANEOUS

TORONTO REFRESHER COURSE

Dr. Ramon Castroviejo of New York City and Dr. Lawrence R. Boies of Minneapolis, Minnesota, will be the guest speakers at the combined refresher course in ophthalmology and otolaryngology, University of Toronto, Faculty of Medicine, to be held January 24 to 29, 1949. Dr. Castroviejo will lecture on cataract surgery and give a surgical clinic; Dr. Boies will speak on general problems of interest in the practice of otolaryngology.

GILL GRADUATE COURSE

Gill Memorial Eye, Ear and Throat Hospital presents its 22nd annual spring graduate course in ophthalmology, otology, rhinology, laryngology, faciomaxillary surgery, bronchoscopy, and esophagoscopy, from April 4 to 9, 1949.

Guest speakers include the following: Dr. Banks Anderson, Dr. H. W. Brown, Dr. W. B. Clark, Dr. W. B. Dearring, Dr. W. W. Eagle, Dr. Harold Falls, Dr. E. P. Fowler, Jr., Dr. Leslie Gay, Prof. L. B. Garrod, Dr. Glen G. Gibson, Dr. C. L. Jackson, Dr. Carl C. Johnson, Dr. A. C. Jones, Dr. Harold H. Joy, Dr. Peter Kronfeld, Dr. John S. Lundy, Dr. Louis Panfique, Dr. Peter N. Pastore, Dr. Bernard Samuels, Dr. E. W. Sheldrup, Dr. Albert E. Sloane, Dr. Claire L. Straith, Dr. A. Earl Walker, Dr. Henry Williams, and Mr. L. A. Watson.

This course is open only to qualified physicians and requests for registration should be addressed to: Dr. E. G. Gill, Gill Memorial Hospital, 711 South Jefferson Street, Roanoke, Virginia.

SOCIETIES

READING MEETING

The 84th meeting of the Reading Eye, Ear, Nose, and Throat Society was held October 27th. This was an "Academy Meeting." The following reported on courses taken in Chicago: Dr. John J. Penta, Dr. Harold L. Strause, Dr. Benjamin F. Souders, Dr. Philip R. Wiest, and Dr. Paul C. Craig.

AKRON ACADEMY MEETS

The Akron Academy of Ophthalmology and Otolaryngology had its first meeting on November 1st. The speaker was Dr. James H. Allen, professor of ophthalmology at the University of Iowa, who discussed, "Bacteriology of Infectious Diseases as They Involve the Eye, Internal and External." The paper was illustrated with lantern slides and was excellently done. A number of ophthalmologists from Cleveland and surrounding communities were present making a total attendance of 35. The following are the officers for the organization for the year 1948-1949: president, Dr. Vincent C. Malloy; vice-president, Dr. Clair E. Anderson; and secretary-treasurer, Dr. A. L. Peter.

WASHINGTON SOCIETY OFFICERS

New officers of the Washington, D.C., Ophthalmological Society are: president, Dr. Jerome A. Sansoucy; vice-president, Dr. J. Thomas Schnebly; secretary-treasurer, Dr. Thomas A. Egan; directors, Dr. Everett S. Caldemeyer and Dr. Edward J. Cummings.

On November 1st the society held a joint dinner meeting with the Baltimore Ophthalmological Society at the Kennedy-Warren Hotel in Washington. The next meeting will be held on January 3rd. The February meeting, date to be announced, will be held jointly with those attending the George Washington University postgraduate course. In March there will be another joint meeting with the Baltimore society, and the final program of the year will be presented on May 2nd.

PERSONALS

PROFESSOR JOSEPH MELLER

To celebrate Professor Meller's 75th birthday a collection of scientific articles is planned. Since at the present time contributions in German periodicals are necessarily limited in number, articles will be accepted for the *Festschrift* which have appeared in any periodical provided that the article was printed with the dedication to Dr. Meller's 75th birthday. Reprints of such original articles could then be bound in one volume and could serve as a *Festschrift*. Notice of such an article should be sent to Prof. J. Böck, Augenklinik, Graz, Austria.

Dr. Derrick Vail, professor of ophthalmology, Northwestern University Medical School, Chicago, gave The Snyder Ophthalmic Foundation lecture at the International Medical Assembly of the Interstate Post-graduate Medical Association of North America held at Cleveland, Ohio, November 9th to 12th. The subject of Dr. Vail's address was "Exophthalmos."

SUBJECT INDEX

Explanation: Numbers in **boldface** refer to original contributions

A

ABSTRACTS, 110, 237, 355, 490, 632, 749, 883, 1021, 1179, 1334, 1517, 1649
1. Anatomy, embryology, and comparative ophthalmology, 110, 355, 632, 749, 1021, 1179, 1517
2. General pathology, bacteriology, immunology, 110, 356, 633, 1021, 1179, 1517
3. Vegetative physiology, biochemistry, pharmacology, toxicology, 111, 237, 357, 634, 749, 1023, 1179, 1518
4. Physiologic optics, refraction, color vision, 112, 239, 359, 637, 756, 1026, 1181, 1523
5. Diagnosis and therapy, 117, 240, 363, 490, 642, 759, 1030, 1182, 1528
6. Ocular motility, 119, 242, 365, 491, 643, 761, 1035, 1183, 1334, 1532
7. Conjunctiva, cornea, sclera, 121, 245, 366, 492, 644, 762, 883, 1037, 1184, 1335, 1534, 1649
8. Uvea, sympathetic disease, aqueous, 125, 247, 370, 495, 645, 767, 884, 1042, 1186, 1337, 1654
9. Glaucoma and ocular tension, 126, 248, 371, 496, 646, 769, 885, 1042, 1187, 1339, 1657
10. Crystalline lens, 129, 250, 374, 498, 647, 889, 1044, 1187, 1340, 1659
11. Retina and vitreous, 132, 251, 375, 499, 648, 891, 1044, 1188, 1341, 1659
12. Optic nerve and chiasm, 255, 379, 503, 65, 896, 1046, 1188, 1343, 1663
13. Neuro-ophthalmology, 256, 380, 503, 652, 898, 1189, 1343, 1664
14. Eyeball, orbit, sinuses, 258, 384, 503, 654, 900, 1344, 1665
15. Eyelids, lacrimal apparatus, 261, 384, 505, 656, 904, 1347, 1666
16. Tumors, 262, 506, 657, 906, 1350
17. Injuries, 262, 507, 658, 907, 1352, 1668
18. Systemic disease and parasites, 265, 515, 658, 909, 1353, 1669
19. Congenital deformities, heredity, 269, 518, 659, 910, 1358, 1671
20. Hygiene, sociology, education, and history, 270, 519, 659, 912, 1359, 1672

ACCOMMODATION, amplitude of, in Chinese, 1028
Changes due to intestinal parasites, 516
fatigue in, 113
intracapsular, experimental facts in, 1029
measurements of, 191
near point of, 1330
physiopathology of, 1522
research on, 359, 756
spasm of, 361
time, in Horner's syndrome, 758
Acetylcholine, effect on ocular tension, 358
effect on retinal arterial presure, 358
Adaptometry, objective, 1028
Adenoma, of the eyelid, 509
Adie's syndrome, 226, 503, 1344
After-images, positive, 362
Agnostic alexia without agraphia, following trauma, 811
Albucid therapy in blepharitis, 904
ALCOHOL, injections, retrobulbar, 1344
study of ciliary ganglia after, 1531
therapy in corneal transplant complications, 494
Alexia and amnesic aphasia, 1665
with color agnosia, 1665
ALLERGY, Antistine in, 1409
to penicillin, 1490
tuberculous, 1518
Alloplastics, in ophthalmology, 241
Alloxanic diabetes, in experimental cataract, 250
Amaurosis, quinine, 731
AMBLYOPIA, hysterical, 1635
quinine, 1188
toxic, treated by raising oxydative cell metabolism, 1047
Amebic dysentery, eye findings in, 1357
American Academy of Ophthalmology, 53rd session, 1508
Ametropia, form of posterior segment in, 641
Amino-acid deficiency, in rats, 111, 495
Anatomy, of orbital fascia, 1539
ANESTHESIA, local in ophthalmology, 1607
sodium pentothal, 1529
action on the eye, 1025
in cataract extraction, 1187
ANEURYSM, circle of Willis, 257
internal carotid, ophthalmoplegic hemicrania from, 381
intracranial and preretinal hemorrhage, 15
motor palsy caused by, 257
miliary with retinal degeneration, 650
Angioid streaks, 1342
ANGIOMA, of the choroid, 370
of the orbit, 384, 900
of retina, diathermy treatment, 829
Angiomatosis, of retina, 499
Angiosarcoma, of orbit, 453
Angioscotometry, contribution to, 639
ANIRIDIA, from contusion of globe, 511
heredity in, 518, 645
neurocapillary test in experimental, 359
ANISEIKONIA, 333
clinical, 1029
exploration of, 1527
prolonged induction of artificial, 687
test instruments compared, 687
Aniseikonic binoculars, 1030
Anophthalmia, 518
ANTERIOR CHAMBER, delayed postoperative formation of, 1261
epithelial invasion of, 1637, 1659
penetration of BAL into, 636
Tyndall phenomenon in, 1032
Anterior segment, diseases of, 1184
stereophotogrammetric study of, 573
Anistine, in ocular alergy, 1409
Appendix, focus of infection in optic neuritis and iridocyclitis, 495
AQUEOUS HUMOR, antigens and antibodies in, 1022
chemistry of, in glaucoma, 128
entrance of sodium into, 767
influence of arterial pressure on, 768, 1023
osmotic pressure of, 749
outflow pressure, in man, 248
passage of ethyl alcohol from blood into, 1179
physiology of, 1519
purine substances in, 636
Aqueous veins, search for, 105
Arachnodactylia, clinical course of eye complications in, 1359
Arachnoiditis, 383, 898
etiology of, 1663
retrobulbar neuritis in, 867
Argyrosis, experimental, 358
of conjunctiva, 1185
treatment of, 1185
Ariboflavinosis, in eczematous keratitis, 1619
in trachomatous pannus, 952
Arsenicals, optic nerve lesions from, 1669
Artificial eyes, 303
See also under Prosthesis
Asthenopia, 1029
neurocirculatory asthenia in, 266
ASTIGMATISM, acquired inverse, 757
axial or macular retinoscopy in, 638
corneal, in ethmoiditis, 757
heredity in, 1358
influence of torsional movements on axis of, 1251
observations on corneal, 756
optical correction of, 116
subjective astigmatoscopy in, 360
tests for, 239
Atabrine, cause of keratitis, 224

Explanation: Numbers in **boldface** refer to original contributions

Atomic bombing, ocular lesions following, 137
Autonomic nervous system, action of ophthalmic drugs on, 359
Aviation, ophthalmology, 661
Aviator, visual examination in those returning from combat, 1360

B

Bacitracin, in ocular infections, 1070, 1211
BAL, penetration into anterior chamber, 636
Bandages, ophthalmic small, 1306
Banister, Richard, portrait of, 1361
Basedow's hyperophthalmia, 1666
Bee venom, in keratitis, 1336
Behcet's syndrome, 339
BETA IRRADIATION, in glaucoma, 945
in ophthalmology, 339, 760
Biomicroscopy, slit control for, 1166
Blennorrhea, inclusion, virus in, 1179
BLEPHARITIS, Albucid treatment in, 904
penicillin in, 506
staphylococcal, 1347
BLINDNESS, causes of in China, 1360
in Illinois, 1501
in Turkey, 1360
due to cerebral tumor and syphilis, 1189
hysterical, 870
radar in, 271
BLOOD, and plasma, in corneal ulcer, 368
sludged, 633
supply, of the optic nerve, clinical significance, 1
vessels, optic nerve, 1
retinal, angle of bifurcation of, 12
Blood-aqueous barrier, permeability, 357
pharmacology of, 1024
Boeck's sarcoid, 83, 220

due to atabrine, 224
eczematous, due to ariboflavinosis, 1619
filamentosa, 123, 124
interstitial, chorioretinitis with, 247
penicillin in, 368, 1041
luetic, 1040
histologic differentiation between tuberculous, 618

Explanation: Numbers in **boldface** refer to original contributions

KERATITIS (*continued*)
macular with cyclitis, 766
mustard gas, 1037
neuroparalytica, from head injury, 263
placental extract to treat, 1101
rosacea, 1184
superficial punctate, 1534
due to onchocerciasis, 515
KERATOCONJUNCTIVITIS, due to diphtherialike organism, 122
epidemic, 121
in Sassari, 246
in Saxony, 1654
uveo-meningeal syndrome following, 1187
sicca, with chronic polyarthritis, 1652
tuberculids in, 1336
Keratoconus, See under Cornea, conical
Keratomalacia, 123
penicillin and vitamin A to treat, 1652
Keratoplasty, See under Corneal Transplantation
Krug, Ernest F., 742
Krukenberg's spindles, 1494

L

Lacunary system, eye liquids as part of, 237
Lagophthalmos, 717
Lamina cribrosa, 110
LACRIMAL apparatus, ephidrosis of, 656
canal, length of, 1349
stenosis of, treatment, 904
fluid, effect on respiration of bacteria, 1517
gland, changes after pilocarpine injections, 357
involved in lymphatic leukemia, 1492
Mikulicz's disease, 955
tumors of, 904, 1318
lysozymes, action of penicillin on, 1024
passage, blockage of, 1349
tumors of, 905
sac, dacryocystitis of infancy, 773
leishmaniasis of, 1358
study of, after rhinostomy, 507
LENS, abscess between lamina and posterior capsule, 890
and cancer, 561
anterior lentiglobus of, 1340
calculation of reduced surface power, 116
chalcosis of, 463
injuries of, 908
mercury in, 129
metabolism of, and cataract, 357
methylization of normal and cataractous, 1024
opacities in target-cell anemia, 517
intrauterine in origin, 1040
meter for, 1528
subluxated, intracapsular surgery of, 499
Lenticonus, posterior, 228, 457
Lentiglobus, anterior, 1340
Leukemia, lymphatic, with lacrimal gland involvement, 1492
Leukoma adherens associated with glaucoma, 373
Leukosarcoma of the iris, 769
Lewisite burns, specific treatment of, 357
Lichen planus, keratitis associated with, 224
Light Adaptation, perception of movement in, 1526
Lighting in industry, 519
LIMBUS, epithelioma of, 1350
tumors of, 1652
Lindau's disease, 221, 892
Lipemia retinalis, 133, 379
